NOTICE

Veterinary medicine is an ever-changing field. Standard safety precautions must be followed, but as new research and clinical experience broaden our knowledge, changes in treatment and drug therapy may become necessary or appropriate. Readers are advised to check the most current product information provided by the manufacturer of each drug to be administered to verify the recommended dose, the method

and duration of administration, and contraindications. It is the responsibility of the licensed veterinarian, relying on experience and knowledge of the patient, to determine dosages and the best treatment for each individual patient. Neither the publisher nor the author assumes any liability for any injury and/or damage to persons or property arising from this publication.

DEDICATION

This book is dedicated to our parents, who taught us to appreciate the value of education and the utility of knowledge, and to Karen, Abby, Nick, Della, Matt, Dan, Ben, Caitlin, Rance, and Ethan for their endless patience and support.

CONTRIBUTORS

Dorothy M. Ainsworth, DVM, PhD, Dipl ACVIM

Associate Professor of Medicine, College of Veterinary Medicine, Cornell University, Ithaca, New York

Frank M. Andrews, DVM, MS, Dipl ACVIM

Professor and Section Chief, Department of Large Animal Clinical Sciences, College of Veterinary Medicine, University of Tennessee, Knoxville, Tennessee

Michelle Henry Barton, DVM, PhD

Professor, Department of Large Animal Medicine, College of Veterinary Medicine, University of Georgia, Athens, Georgia

Warwick M. Bayly, BVSc, MS, PhD, Dipl ACVIM

Dean, College of Veterinary Medicine, Washington State University, Pullman, Washington

Laurie A. Beard, DVM

Clinical Assistant Professor, Veterinary Clinical Sciences, College of Veterinary Medicine, The Ohio State University, Columbus, Ohio

Joseph J. Bertone, DVM, Dipl ACVIM

Alpine Animal Hospital, Carbondale, Colorado

Anthony T. Blikslager, DVM, PhD, Dipl ACVS

Assistant Professor, Equine Surgery and Gastrointestinal Biology, College of Veterinary Medicine, North Carolina State University, Raleigh, North Carolina

John D. Bonagura, DVM, MS, Dipl ACVIM

Professor, Veterinary Clinical Sciences, College of Veterinary Medicine, The Ohio State University, Columbus, Ohio

Barbara A. Byrne, DVM, PhD, Dipl ACVIM

Assistant Professor of Veterinary Pathology, Department of Veterinary Pathobiology, School of Veterinary Medicine, Purdue University, West Lafayette, Indiana

Elaine M. Carnevale, DVM, MS, PhD

Assistant Professor, Animal Reproduction and Biotechnology Laboratory, Department of Biomedical Sciences, College of Veterinary Medicine and Biomedical Sciences, Colorado State University, Fort Collins, Colorado

Marco A. Coutinho da Silva, DVM, MS, PhD Candidate

Department of Biomedical Sciences, College of Veterinary Medicine and Biomedical Sciences, Colorado State University, Fort Collins, Colorado

Mark V. Crisman, DVM, MS, Dipl ACVIM

Associate Professor, Large Animal Medicine, Department of Large Animal Clinical Sciences, Virginia-Maryland Regional College of Veterinary Medicine, Blacksburg, Virginia

Jennifer L. Davis, DVM, MS, Dipl ACVIM

Graduate Research Assistant, College of Veterinary Medicine, North Carolina State University, Raleigh, North Carolina

Charles Dickinson, DVM, MS, Dipl ACVIM

Assistant Professor of Equine Medicine, Department of Clinical Sciences, College of Veterinary Medicine and Biomedical Sciences, Colorado State University, Fort Collins, Colorado

Patricia M. Dowling, DVM, MS, Dipl ACVIM, ACVCP

Professor, Veterinary Clinical Pharmacology, Director, Canadian gFARAD, Western College of Veterinary Medicine, Saskatoon, Saskatchewan, Canada

PREFACE

The 5 years since the publication of the first edition of *Equine Internal Medicine* have witnessed the continued evolution of equine internal medicine as a specialty veterinary discipline. The progressive globalization of the world's societies and associated growth in the international movement of horses has been linked with increased global expectations in the standard of veterinary care and evaluation of sick horses. The sophistication of specialist training programs and the increased number of equine internists also taking advantage of postgraduate doctoral opportunities have resulted in a wealth of new information and the maturing of an increasingly complex and challenging discipline — equine internal medicine. The delivery of superior health care and increased client expectations that have been associated with the growth of this discipline have led to the development of a specialist, the equine internist, and extremely well-informed and astute equine general practitioners. Partly as a result of more training opportunities, the number of equine internists in practice is growing, and many veterinary teaching hospitals

are now tertiary care facilities rather than secondary referral centers. More than ever before, equine internal medicine now stands as an autonomous specialty in the veterinary profession.

The aim of the first edition of *Equine Internal Medicine* was to promote a clearer comprehension of the principles of disease or problem development by focusing on the basic pathophysiologic mechanisms that underlie the development of various equine diseases. The objectives behind the publication of the second edition of this book are no different. Basic information is presented and then related to the clinical characteristics of each disease and its therapy and management.

All the chapters that appeared in the first edition have been updated and a number of them have been extensively revised. Sections on the mechanisms by which infectious agents establish themselves contain a considerable amount of new material as do those dealing with the diseases of foals, the reproductive system, the endocrine system, and the gastrointestinal tract. In addition, new chapters have been contributed on the epidemiologic approach to outbreaks of disease and critical care of patients, while those on clinical pharmacology have also been rewritten.

Although the bulk of the chapters address specific diseases along systems-based lines, we realize that the practitioner is initially confronted with a specific problem that may have its origin in one or more of the body's systems. The first section of the book is therefore devoted to an in-depth discussion of the basic mechanisms by which the problems may develop and the principles underlying the treatment to many of them. The reader can build on this foundation by reading about specific disorders in the second section of the book, which is divided into chapters dealing with problems of a particular body system or of a specific nature.

Many true experts have contributed to this text. Their depth of knowledge about all aspects of equine internal medicine is encyclopedic. We are grateful for their efforts and diligence in helping us to produce what we hope will come to be regarded as the definitive text on medical diseases of horses. We trust the second edition of *Equine Internal Medicine* will prove to have as much universal appeal and application as the first one.

We would be remiss if we did not thank the many people at Elsevier for their persistence and efforts. Teri Merchant, Liz Fathman, Jody McBride, Cheryl Abbott, John Dedeke, and Linda Duncan particularly deserve our gratitude. They and many others have assisted in manuscript preparation, correspondence, and all the other tasks that must be accomplished to get a book like this into print. Without them and the generosity of our colleagues, this book would not have been published. We trust that everyone's efforts have been worthwhile.

1 # CHAPTER 1 THE EQUINE IMMUNE SYSTEM

1.1 ## 1.1—Equine Immunology

D. Paul Lunn

David W. Horohov

Although much of modern immunology has focused on human beings and murine models of human diseases, the horse has played a significant role in the understanding of immunological processes. These contributions include the earliest work on serotherapy and passive transfer, immunoglobulin structure and function, immunity to infectious agents, immunodeficiencies, and more recently, reproductive immunology. Work in the horse continues in many of these areas in equine medicine and comparative immunology. The overall organization and function of the equine immune system is similar to other mammalian species, though differences exist. The reader is referred to any one of a number of texts[1–4] for a more in-depth summary of immunology. This chapter focuses on those aspects of the immune system of most interest to equine researchers and clinicians. When possible, pertinent references to equine work are provided.

1.1.1 ### Innate Immunity and the Acute Inflammatory Response

Immune defenses include *innate responses* and *adaptive responses,* each mediated by cellular and soluble components. Although the innate and adaptive responses often are regarded as separate, they in fact are related intimately, sharing many of the same processes and components. The major difference lies in the specificity and recall capability that characterize the adaptive response. The specificity of adaptive responses, mediated by antibodies or by effector cells such as cytotoxic T lymphocytes (CTLs), and the phenomena of immunological memory are responsible for the capacity to protect an animal completely against a particular pathogen. Nevertheless, the role of innate responses in prompting the adaptive response and providing valuable time for specific adaptive responses to develop cannot be overstated.

The horse, like every other species, is under constant assault from a variety of microbes that share its living space. Although most of these organisms are harmless, their disease-causing potential is evident when they cause opportunistic infections in individuals with compromised immune systems.[5] Mammals have evolved a variety of defensive measures to prevent infection. The first line of defense includes the physical barriers of the skin and mucosal surfaces of the digestive, respiratory, and urogenital tracts. In addition to providing a barrier to penetration, the surface of the skin contains various enzymes, fatty acids, and oils that inhibit the growth of bacteria, fungi, and viruses. Mucous membranes and mucosal secretions contain bacteriolytic enzymes, bactericidal basic polypeptides, mucopolysaccharides, and antibodies that prevent colonization and penetration of these surfaces. Mucus also provides a physical barrier that entraps invading organisms and leads to their eventual 2
disposal.[6] Particles trapped in the mucous secretions of the respiratory tract, for example, are transported upward through the action of ciliary cells to the trachea where they are swallowed.[7] Once the particles are swallowed, the acidic secretions and digestive enzymes of the stomach destroy most organisms. Normal epithelial and tissue architecture is essential for successful exclusion of bacteria, and the disruption of this mechanism makes the host susceptible to infection by bacteria that normally colonize the upper airway.[8,9]

1.1.1.1 ACUTE PHASE PROTEINS, PROINFLAMMATORY CYTOKINES, AND COMPLEMENT

Once the integumentary and mucosal barriers are breached, the host presents a variety of internal defenses to contain and eliminate potential pathogens. Invading organisms can initiate an inflammatory response via the activation of plasma protease systems directly, such as by bacterial cell wall components, or by the secretion of toxins or other proteins that can activate the inflammatory response directly. Injured cells also release products that initiate plasma protease cascades or produce proinflammatory cytokines that augment the inflammatory process. Resident macrophages that encounter invaders complement the inflammatory response through the production of proinflammatory cytokines such as interleukin-1 (IL-1), IL-6, and tumor necrosis factor α (TNF-α).[10] Cytokines are hormonelike proteins that mediate a variety of cellular responses. A vast number of cytokines are involved in the regulation of innate and adaptive immune responses. IL-1, for example, is a pleiotropic mediator of the host response to infections and injurious insults (Box 1.1-1). Many of the effects of IL-1 are mediated through its capacity to increase the production of other cytokines, such as granulocyte colony-stimulating factor, TNF-α, IL-6, IL-8, platelet-derived growth factor, and IL-11 (see the following discussion of cytokines, chemokines, and interleukins). IL-6 is responsible for the increased production of *acute phase proteins* (Table 1.1-1) by the hepatocytes. Although the function of all of the acute phase proteins remains unclear, many of these proteins and the cytokines that elicit them are responsible for the characteristic physical signs of inflammation, including increased blood flow and vascular permeability, migration of leukocytes from the peripheral blood into the tissues, accumulation of leukocytes at the inflammatory focus, and activation of the leukocytes to destroy any invading organisms.[11] The acute phase proteins include a number of *complement* proteins. The complement system is an interacting series of proteases and their substrates that produce the physiologically active intermediaries that can damage membranes, attract neutrophils and other cells, increase blood flow and vascular permeability, and opsonize bacteria and other particles for phagocytosis.[12] The complement cascade can be activated in two ways (Figure 1.1-1). The *classical pathway* involves the recognition and binding of the first component of complement (C1) to antigen-antibody complexes. Bound C1 is proteolytic and cleaves C4. This cleavage of C4 leads to the binding of C2 to C4b. C2 in turn is cleaved by C1 into C2a. The C4bC2a complex is referred to as the classical pathway C3 convertase because the complex is a protease capable of cleaving C3 into C3a and C3b. Another C3 convertase is generated via the alternate pathway. The activation of complement via the *alternate pathway* does not involve antibodies; instead, certain microbial products (zymosan and lipopolysaccharide) stimulate the association of factor D, a proteolytic enzyme, with the complex of factor B and C3b leading to the formation of the C3bBb complex, which is the alternative pathway C3 convertase. C3a and C4a can bind to mast cells, causing them to degranulate, and are referred to as anaphylatoxins. C3b serves as an opsonin for C3b receptor–bearing phagocytic cells. C3b also is required for the formation of the membrane attack complex by the terminal complement components C5 to C9. In this process C5 is cleaved by the C4b2a3b (classic pathway C5 convertase) or by C3b, Bb, and properidin (alternate pathway C5 convertase). C5 is cleaved into C5a and C5b. C5a is a chemoattractive factor for neutrophils and monocytes.[13] C5b forms a complex with C6, C7, and C8 on cell surfaces, which leads to the insertion and polymerization of C9 that forms a pore in the membrane leading to cell lysis.

1.1.1.1.1 BOX 1.1-1 BIOLOGIC ACTIVITIES OF I NTERLEUKIN-1

Activates T cells.

Activates B cells.

Enhances natural killer cell killing.

Activates fibroblast growth factor.

Stimulates prostaglandin E synthesis.

Stimulates bone resorption.

Is chemotactic for neutrophils.

Activates osteoclasts.

Induces fever.

Is cytotoxic for some tumor cells.

Is cytostatic for other tumor cells.

Stimulates collagen production.

Stimulates keratinocyte growth.

Stimulates mesangial cell growth.

Activates neutrophils.

Induces interleukin-6 production.

2

TABLE 1.1-1 Acute Phase Proteins

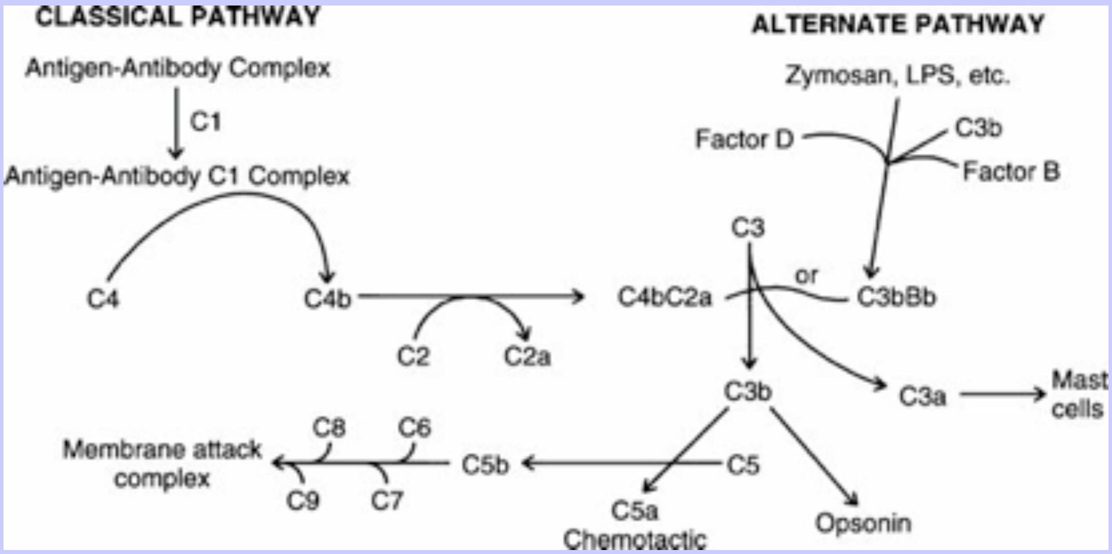
NAME	FUNCTION
C3, C4, and factor B	Opsonins
C-Reactive protein	Opsonin and complement activator
Fibrinogen	Fibrin precursor and clotting factor
Kininogen	Kinin precursor
α1-Acid glycoprotein	Function unknown; possibly immunomodulatory
Ceruloplasmin and ferritin	Iron restriction
Haptoglobin	Binding free hemoglobin
Hemopexin	Binding free heme
Serum amyloid A	Lipid transporter; possible inhibitor of neutrophil function
Serum amyloid P	Lipid transporter; possible inhibitor of neutrophil function
α1-Antichymotrypsin	Protease inhibitor
α2-Macroglobulin	Protease inhibitor
Cysteine protease inhibitor	Protease inhibitor

1.1.1.2

LIPID MEDIATORS

Prostanoids are lipid mediators that regulate the inflammatory response.[14,15] The prostanoid group includes the prostaglandins, leukotrienes, and prostacyclin; these are the products of cyclooxygenase cleavage of arachidonic acid followed by endoperoxidation (Figure 1.1-2). The major sources of prostanoids in acute inflammation are phagocytes, endothelial cells, and platelets. Although prostanoids in general mediate the cardinal effects of pain, fever, and edema characteristic of the acute inflammatory response, their particular roles are confounding and can be pro- or antiinflammatory (Table 1.1-2).[16] Prostanoid production depends on the activity of the two isoforms of the cyclooxygenase enzymes within cells: COX-1, which is present in most cells and the expression of which is generally constitutive, and COX-2, the expression of which is low or undetectable in most cells but increases dramatically on stimulation, particularly in cells of the immune system. Increased COX-2 expression by inflammatory stimuli likely accounts for the high levels of prostanoids found in chronic inflammatory lesions and is the basis for the development of COX-2–specific inhibitors for treating chronic inflammatory diseases. However, studies using mice have indicated that the earliest prostanoid response to deleterious environmental stimuli depends on COX-1, and only as the inflammatory process progresses does COX-2 become the major source of prostanoids.[17] As such, recent emphases on developing specific COX-2 inhibitors as treatments for inflammatory diseases may need to be reconsidered.[18]

Figure 1.1-1 Classical and alternate pathways of complement activation (see text for explanation). *LPS,* Lipopolysaccharide.



Both COX isoforms produce prostaglandin H_2 (PGH_2), which is the common substrate for a series of specific synthase enzymes that produce PGD_2, PGE_2, PGF_2, PGI_2, and thromboxane A_2 (see Figure 1.1-2). The differential expression of these enzymes within cells present at sites of inflammation determines the profile of prostanoid production. For example, mast cells predominantly generate PGD_2, whereas resting macrophages produce thromboxane A_2 in excess of PGE_2, though this ratio changes to favor PGE_2 production after activation. Likewise, the biological effect of a prostanoid depends on binding to G protein–coupled cell-surface receptors. The receptors for PGF_2, PGI_2, and thromboxane A_2 are called FP, IP, and TP, respectively. In contrast, PGD_2 acts through two receptors, the DP receptor and the recently identified CRTH2 receptor, and PGE_2 has four subtypes of receptors, termed EP1 to EP4. The prostanoid receptors themselves are coupled to various G protein–coupled intracellular signaling pathways. The DP, EP2, EP4, IP, and one isoform of the EP3 receptor can couple to G_s and thus increase the intracellular cyclic adenosine monophosphate concentration. In 3
T cells and other inflammatory cells, coupling generally is associated with inhibition of effector cell functions. 4
By contrast, the EP1, FP, IP, and TP receptors, as well as other EP3 iso forms, couple to G_q. Activation of these receptors leads to increased intracellular calcium concentrations and immune cell activation. Finally, TP, CRTH2, and yet another EP3 receptor isoform each can couple to G_i, causing cyclic adenosine monophosphate levels to decline while mobilizing intracellular calcium. Many cells of the immune system express multiple 4
receptors that couple to these apparently opposing pathways. The array of receptors the cells express and the 5
intracellular pathways to which they are coupled determine the impact of prostanoids during an inflammatory response. Activation of these receptors, even when coupled to similar pathways, might evoke different responses because of differences in the levels of expression (constitutive and induced) or in the patterns of desensitization. The role of prostanoids in a given inflammatory response depends not only on the presence of the lipid mediators in the lesion but also on the receptor profile on immune cells and the biochemical signaling pathways of these receptors.[17] Thus PGE_2 is considered proinflammatory because it promotes vasodilation by activating cyclic adenosine monophosphate–coupled EP2 receptors on vascular smooth muscle and increases

vascular permeability indirectly by enhancing the release of histamine and other mediators from tissue leukocytes such as mast cells. Prostaglandin E_2 is also the prostanoid responsible for development of fever. As inflammation progresses, increased expression of COX-2 and prostaglandin-E synthase enhance PGE_2 synthesis by macrophages. Increased PGE_2 inhibits leukocyte activation and mast cell degranulation and relaxes smooth muscle contractions. In the lung, PGE_2 promotes bronchodilation through activation of G_s-coupled EP2 and EP4 receptors. In these situations, PGE_2 may be considered antiinflammatory.

Figure 1.1-2 Lipid mediators of inflammation (see text for explanation). *HPETE,* Hydroperoxyeicosatetraenoic acid; *HETE,* hydroxyeicosatetraenoic acid; *LTA_4,* leukotriene A_4. (From Davies P, Bailey PJ, Goldenberg MM et al: The role of arachidonic acid oxygenation products in pain and inflammation, *Annu Rev Immunol* 21:337, 1984. TABLE 1.1-2 Physiologic Effects of Lipid Mediators

	LIPID MEDIATOR*									
EFFECT	PGD_2	PGE_2	$PGF_{2\alpha}$	PGI_2	TXA_2	LTB_4	LTC_4	LTD_4	LTE_4	PAF
Constricts smooth muscle	X		X	X	X	X	X	X	X	X
Dilates systemic vasculature	X									
Increases vascular permeability	X			X		X	X	X	X	X
Inhibits platelet aggregation	X			X						
Aggregates platelets					X					X
Increases vasodilation									X	
Regulates arteriolar constriction and vasodilation							X	X		
Increases mucus production							X			X
Provides chemoattractant for neutrophils						X				
Inhibits leukocyte chemotaxis		X								
Relaxes smooth muscles		X								
Inhibits mediator release		X								
Stimulates mediator release						X				X

* *PGD_2,* Prostaglandin D_2; *PGE_2,* prostaglandin E_2; *$PGF_{2\alpha}$,* prostaglandin $F_{2\alpha}$; *PGI_2,* prostaglandin I_2; *TXA_2,* thromboxane A_2; *LTB_4,* leukotriene B_4; *LTC_4,* leukotriene C_4; *LTD_4,* leukotriene D_4; *LTE_4,* leukotriene E_4; *PAF,* platelet-activating factor.

1.1.1.3

CHEMOTAXIS AND LEUKOCYTE TRAFFICKING

One of the initial and most crucial aspects of the acute inflammatory response is the recruitment of leukocytes (primarily neutrophils) to the site of injury. Neutrophils constitute the first line of cellular defense and are the

initial cells involved in an inflammatory response. These phagocytic cells are derived from multipotent stem cells located chiefly in the bone marrow. Under the influence of a variety of signals provided from within and without the bone marrow, these stem cells become committed to developing into cells of the granulocyte lineage. The critical signal is provided by a family of growth factors known as *colony-stimulating factors* that provide proliferative and differentiative signals leading to the development of granulocytes and other leukocytes. Once released into the circulation, these cells must find their way to the site of the inflammatory response. The production of various chemotactic factors by host cells, bacteria, and other invaders causes various leukocytes to enter the circulation and to be carried to the site of the injury.[19] Chemokines are soluble proteins produced by host cells that induce the directional migration and activation of leukocytes, as well as other somatic cell types, and thus play a major role in the inflammatory response. IL-8 plays a central role in this process. Other chemokines promote humoral and cell-mediated immune reactions; regulate cell adhesion, angiogenesis, leukocyte trafficking, and homing; and contribute to lymphopoiesis and hematopoiesis.[20]

The specific trafficking of leukocytes from the blood to inflammatory sites depends on the production of chemotactic factors and the interaction of specific receptors on the leukocytes with corresponding adhesion molecules on the endothelial surface of the blood vessels. Neutrophil adherence is a two-step process first involving endothelial cell surface molecules known as selectins.[10] Small venular endothelium overlying a site of inflammation and exposed to thrombin, platelet-activating factor, IL-1, histamine, or other mediators released by clotting, platelet activation, or mast cell activation expresses P-selectin.[21] P-selectin mediates the process in which neutrophils initially interact with the endothelial surface. In a process known as rolling, the circulating neutrophil interacts with the endothelial cell before actual adherence.[22] Selectins bind to carbohydrate ligands present on the cell surface. In the case of neutrophils the ligand is sialylated Lewis-X antigen for the endothelial E-selectin. The second part of the adherence process is the tight binding of integrins on the neutrophil surface with intracellular adhesion molecules on the endothelial cell surface. Leukocyte integrins are heterodimeric proteins with distinct α and shared β polypeptide chains. The α and β chains can combine in different heterodimers to form multiple shared and unique specificities (Table 1.1-3). Neutrophil expression of $\alpha_M\beta_2$ and $\alpha_X\beta_2$ is activation-dependent. Neutrophils can be activated by a number of soluble proteins including formylmethionylleucylphenylalanine, N-formylated peptides present in bacterial but not eukaryotic proteins. Host factors present at the site of inflammation—notably the complement proteins (C5a and C3a), cytokines such as IL-8 and TNF, and immune complexes—also can activate neutrophils.[23] Expression of integrins by the activated neutrophil allows tethering to the endothelial surface. The migration of neutrophils through the vascular wall is less well understood than these initial events leading to firm adhesion. The β_2 integrins—as well as $\alpha_V\beta_3$, platelet/endothelial cellular adhesion molecule-1, and integrin-associated protein—appear to play a role in this process. Endothelial cell–produced IL-8 also is believed to have a critical role in this process. Once through the endothelium, phagocytes may adhere to other cells during migration to the site of inflammation. These interactions also depend on $\alpha_M\beta_2$ and $\alpha_X\beta_2$ integrins. Migration through the extracellular matrix is mediated by $\beta_1\beta_3$ and β_5 integrins recognizing specific protein ligands.

Neutrophils recruited and activated in this manner actively phagocytose microscopic invaders and attempt to destroy them using reactive oxygen products generated via an NADPH-oxidase-dependent “respiratory 5
burst.”[22,24] In this process, neutrophils release additional proinflammatory mediators, amplifying this response. 6
Among those cells attracted to the area are *natural killer* cells capable of lysing virus-infected and other abnormal cells. The production of interferon-α and interferon-β by macrophages and other cells enhances the cytolytic activity of the natural killer cells, which can be the source of interferon-γ, another proinflammatory cytokine. Depending on the magnitude of the initial insult and the susceptibility of the invader to neutrophil-mediated destruction, the inflammatory response may be acute or chronic.

TABLE 1.1-3 Integrins and Their Ligands

INTEGRIN PROTEINS	EXTRACELLULAR MATRIX PROTEINS	CELL SURFACE*
β_1 SUBFAMILY		
$\alpha_1\beta_1$	Collagen, laminin	
$\alpha_2\beta_1$	Collagen, laminin	
$\alpha_3\beta_1$	Collagen, laminin, fibronectin	
$\alpha_4\beta_1$	Fibronectin	VCAM-1, MAdCAM-1
$\alpha_5\beta_1$	Fibronectin	
$\alpha_6\beta_1$	Laminin	
$\alpha_7\beta_1$	Fibronectin, vitronectin	
β_2 SUBFAMILY		
$\alpha_L\beta_2$		ICAM-1, ICAM-2, ICAM-3
$\alpha_M\beta_2$	C3bi, factor X, fibrinogen	ICAM-1
$\alpha_X\beta_2$	C3bi, fibrinogen	ICAM-1 (?)
$\alpha_D\beta_2$		ICAM-3
β_3 SUBFAMILY		
$\alpha_V\beta_3$	Vitronectin, fibronectin, von Willebrand factor, finbrinogen, laminin, thrombospondin	PECAM-1
β_4 SUBFAMILY		
$\alpha_6\beta_4$	Laminin	
β_7 SUBFAMILY		
$\alpha_4\beta_7$	Fibronectin	MAdCAM-1, VCAM-1
$\alpha_E\beta_7$	E-cadherin	

* *VCAM*, Vascular cell adhesion molecule; *MAdCAM*, mucosal addressin cell adhesion molecule; *ICAM,* intracellular adhesion molecule; *PECAM*, platelet/endothelial cellular adhesion molecule.

Acute inflammation is a rapid response to an injury, characterized by accumulation of fluid, plasma proteins, and neutrophils that rapidly resolves once the initial inflammatory stimulus is removed. Deactivation signals include PGE_2, cortisol, IL-10, and transforming growth factor β (TGF-β). Some of those chemotactic agents responsible for initiating the response (IL-8, N-formyl-methionyl-leucyl-phenylalanine, C5a, leukotriene B4, and platelet-activating factor) also serve to downregulate its intensity by inducing the shedding of IL-1 receptors from neutrophils.[25] The shedding of this decoy receptor may have antiinflammatory effects as it

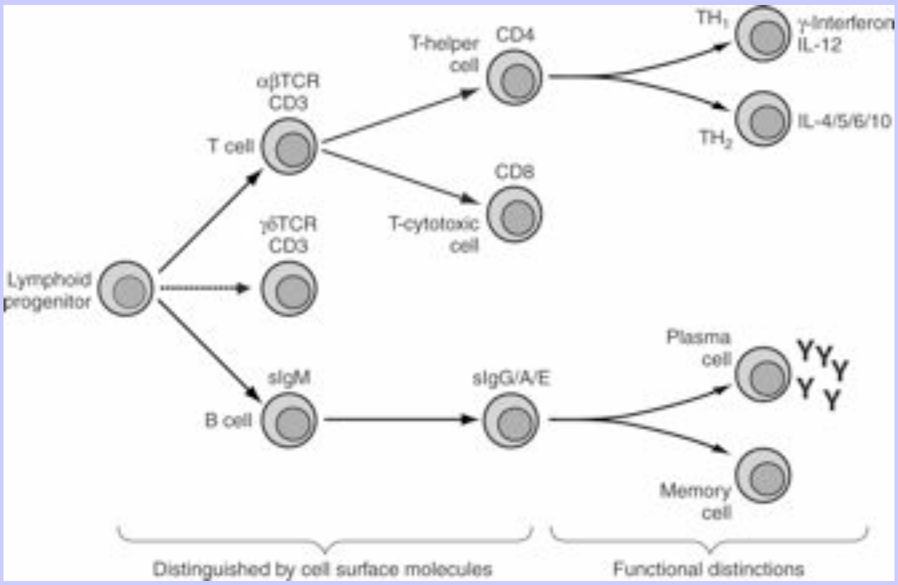
effectively binds and neutralizes this cytokine. Likewise, many acute phase proteins may have immunomodulatory activity, downregulating neutrophil function.[26] Acute inflammatory responses often may be subclinical and resolve without complications. However, if the invader is resistant to neutrophil-mediated destruction or the degree of injury is great, the response may become more chronic with the added recruitment of macrophages and lymphocytes and growth of fibroblasts.

The essential characteristic of the innate immune response is that it does not exhibit specificity for the invading organism. The induction of an innate immune response does not require prior exposure to the invading organism and is not augmented by repeated exposure to the same organism. Although resistance may be controlled genetically, the genes encoding resistance are not found within the gene complex that controls adaptive immune responses. In most instances, these mechanisms are adequate for eliminating casual invaders. However, pathogenic organisms have evolved various methods for avoiding elimination. In response to these organisms, the specialized cells and products of the adaptive immune response are mobilized.

1.1.2 Adaptive Immunity

The adaptive immune response follows an encounter with a foreign agent and depends on antigen-specific 6
immune responses mediated by different divisions of the lymphocyte family (Figure 1.1-3). In contrast to the 7
nonspecific nature of the innate immune response, an important characteristic of the adaptive immune response is its specificity. Exposure of the host to a particular microbe or parasite results in the induction of immune responses that are directed against specific components of the invading organism that do not affect unrelated organisms. The specificity of the adaptive immune response results from the interaction of specific molecular structures or *antigens* of the invader with antigen-specific receptors on lymphocytes. All types of chemical structures can serve as antigens; however, not all antigens can induce an immune response. *Immunogens,* those antigens that can stimulate an immune response, are usually chemically complex molecules of high molecular weight. Proteins, nucleic acids, lipids, and polysaccharides all can serve as immunogens. Large immunogens such as proteins contain multiple *antigenic determinants* or *epitopes* that interact with lymphocytes via their antigen-specific receptors. *Haptens* consist of single antigenic determinants and can combine effectively with the binding site of antibody molecules. However, because they consist only of a single antigenic determinant, they cannot cross-link B cell receptors (antibody molecules) and they are also unable to stimulate T cell responses. Haptens therefore cannot stimulate an immune response unless multiple haptens are attached physically to a larger molecule known as a *carrier*. Though these distinctions between antigens, haptens, and immunogens appear minor, they provide the underlying basis for understanding many allergic and autoimmune responses.

Figure 1.1-3 Major divisions of the lymphocyte family. To the left of the diagram different populations of lymphocytes are distinguished by expression of different cell surface molecules. To the right of the diagram the distinctions are functional.

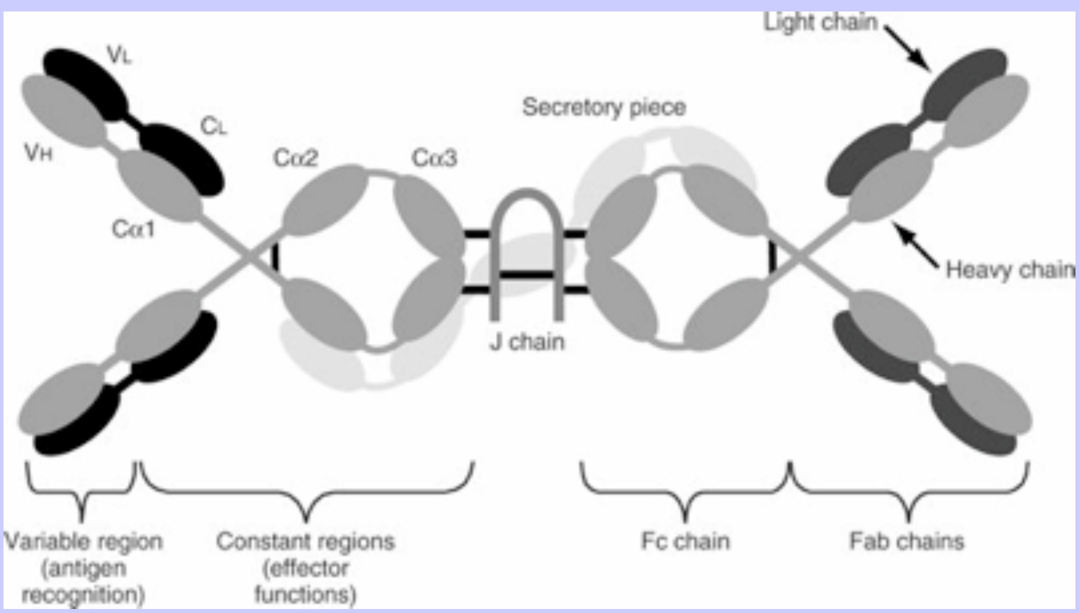


Like the innate response, the adaptive immune response to a specific antigen consists of humoral and cellular effector mechanisms. The humoral component is mediated by *immunoglobulins* or *antibodies* found in plasma and tissue fluids. Antibodies are produced by B lymphocytes, small lymphoid cells characterized by the cell surface expression of immunoglobulin molecules. B cells represent less than 15% of circulating peripheral blood mononuclear cells but are present in higher proportions in lymph nodes and spleen. B cells are derived from the fetal liver and bone marrow of mammals and the bursa of Fabricius of birds. In the bone marrow, B cells are the products of a putative lymphoid stem cell derived from the pluripotent stem cell. Under the influence of various cytokines produced by bone marrow *stromal* cells, the B cell precursor undergoes its 3-day development into a mature B cell. On stimulation with specific antigen, B cells differentiate into *plasma cells* that produce enormous quantities of specific antibody. The activation, proliferation, and differentiation of B lymphocytes into plasma cells depends on other cells, including T lymphocytes, which represent the cellular component of the adaptive
immune response. The T lymphocyte also is derived from the multipotent stem cell and lymphoid precursor in the 7
bone marrow, though its subsequent development into the mature T cell occurs in the *thymus*. Within the thymic 8
environment, prothymocytes undergo a developmental and selective process while emigrating through the cortex into the medullary region of the thymus. Less than 3% of all immature thymocytes in the cortex survive to become peripheral T cells.

Although the induction of an antibody response requires the interaction of B and T lymphocytes, these cells recognize different epitopes on the same antigen. Indeed, antigen recognition by B cells and T cells is fundamentally different. B cells and antibodies recognize antigens in solution or on cell surfaces in their native conformation, whereas T cells only recognize antigen in association with self-molecules known as *major histocompatibility complex* antigens found on most cell surfaces. The adaptive immune response thus differs from

innate immunity in that it is antigen driven. Those cells that mediate the adaptive immune responses, T and B lymphocytes, express specific receptors for the antigen. Because the immune system responds to antigens of live and killed pathogens, stimulating immunity without causing infection is possible and is the basis of vaccination. Although this principle appears to be straightforward, vaccination does not always yield the expected result. Why some vaccines work and others fail is a complex issue, a major component of which is the nature of the antigen-specific receptors of lymphocytes.

Figure 1.1-4 Molecular structure of secretory immunoglobulin A. This schematic illustrates the major features of immunoglobulin molecules. Although the illustrated IgA molecule is dimeric, with the two immunoglobulin units joined by a J chain and a series of disulphide bonds, IgG molecules are monomeric. Each immunoglobulin unit consists of two heavy chains and two light chains. The heavy chains have four subunits, and the light chains have two. One end of the immunoglobulin unit has a highly variable protein structure and is involved in antigen recognition, whereas the remainder of the immunoglobulin unit has a constant structure in each immunoglobulin class and subclass. This structure determines the functional characteristics of the molecule, such as binding complement or recognition by macrophages or neutrophil Fc receptors. This specialized dimeric IgA molecule also has a secretory piece that increases its stability in the harsh mucosal environment.



1.1.2.1 IMMUNOGLOBULIN: ANTIGEN-SPECIFIC RECEPTOR OF B LYMPHOCYTES

The antigen-specific receptor of the B cell is cell surface–bound antibody. An antibody molecule is composed of two identical light chains and two identical heavy chains that form a disulfide-linked Y-shaped molecule (Figure 1.1-4). The light chain can be divided into two domains, a conserved carboxy-terminal domain and a highly variable amino-terminal domain. Analysis of heavy chains reveals a similar domain structure with the amino-terminal domain being highly variable and the presence of three constant domains. The antigen-binding region of an antibody molecule is formed by the association of the amino ends of a light and a heavy chain, whereas the carboxyl end of the heavy chain determines the isotype of the molecule. Five different *isotypes* of antibody molecules have been identified in most species: immunoglobulin D (IgD), IgM, IgG, IgA, and IgE (Table 1.1-4), although evidence for the existence of IgD in horses currently is lacking.[27] Additionally, the IgG 8
isotype can be subdi vided into subclasses based on physiochemical properties. Restriction analysis of equine 9
genomic DNA has indicated the existence of one IgE, one IgA, and up to six IgG genes.[28] Four IgG subclasses have been previously identified serologically as IgG(a), IgG(b), IgG(c), and IgG(T).[29] The IgG(a) is tentatively identified as the first IgG gene, IgG(T) as the third IgG gene, and IgG(b) as the fourth IgG gene.[28,29a] The serological identification of the remaining genes has not yet been accomplished.

TABLE 1.1-4 Immunoglobulin Isotypes

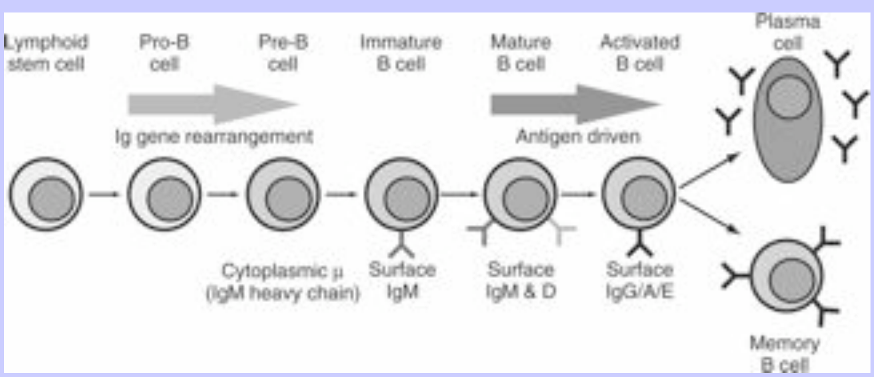
ISOTYPE	IMMUNOLOGICAL FUNCTION
IgD	Antigen receptor of naïve B lymphocytes. Currently no IgD heavy chain gene has been identified in the horse.
IgM	Surface IgM is found on naïve, activated, and memory B cells. Secreted IgM is a pentamer and represents the major antibody produced during a primary response. IgM efficiently mediates agglutination, neutralization, opsonization, and complement activation.
IgG	IgG is the principle immunoglobulin found in plasma, representing up to 80% of the total immunoglobulin concentration. Various subclasses of IgG have been identified (see text). Four IgG subclasses occur in the horse (IgGa, IgGb, IgGc, and IgG[T]) as defined by current monoclonal antibodies, although six IgG heavy chain genes have been identified.[29a] The major functions of IgG include opsonization and neutralization reactions. IgGa and IgGb are effective in fixing complement and participate in antibody-dependent cellular cytotoxicity, whereas IgGc and IgG(T) are not effective, although they appear to play an important role in exotoxin neutralization and immunity to parasites.
IgA	IgA, the most abundant antibody in secretions (tears, mucus, saliva, colostrum, etc.), is a dimer composed of two IgA molecules joined by a J chain. IgA in the plasma is predominantly monomeric. IgA antibodies can be neutralizing but only activate complement via the alternative pathway.
IgE	Most IgE is found associated with the surface of mast cells and basophils and only small amounts are present in the plasma. The cross-linking of two IgE molecules with specific antigen results in the degranulation of the mast cells and basophils. Thus IgE is the primary antibody responsible for type I hypersensitivity reactions and appears to play a central role in immunity to parasites.

Membrane-bound IgM and IgD serve as the antigen-specific receptors for B lymphocytes. Each contains a membrane spanning region near its carboxy end that is inserted into the messenger RNA during differential splicing of the heavy chain exons. Although rarely detectable in the circulation, IgD is present in large quantities on the surface of naïve B lymphocytes. Following activation, the surface expression of IgD is lost, though the cell may continue to express the membrane form of IgM. Early in an immune response the B cell secretes large amounts of the pentameric form of IgM. As the immune response proceeds, the B cell switches the isotype of its heavy chain. Isotype switching involves the substitution of one heavy chain constant region for another. The genes encoding the five different constant regions of the heavy chain are sequentially arranged on the chromosome (Cδ, Cμ, Cγ, Cε, and Cα). Initially, the first two constant region genes encoding the δ and μ constant regions are used to form the heavy chain. The 5′ region of each constant region gene segment contains repetitive regions of DNA known as *switch sequences*.[30] The switch sequences appear to play a role in this rearrangement and may serve as the target for specific recombinases. When switching occurs, a new constant region segment is selected and the intervening genes are removed by splicing or looping out. Isotype switching only affects the heavy chain constant domains and has no effect on the antigen specificity of the immunoglobulin molecule. The signals for B cells to undergo isotype switching are provided by T lymphocytes in the form of various cytokines.[31] For example, IL-4 induces isotype switching to the IgE isotype, whereas interferon-γ blocks this induction and augments IgG production.[32,33] IgA is produced in response to the combination of the cytokines IL-4, IL-5, and TGF-β.[34]

The combination of the variable domains of the light and heavy chains determines the antigen specificity of a particular antibody molecule (and the B cell that produces it). The association of these two domains results in the formation of an antigen-binding groove or pocket that contains regions of hypervariability that define the specificity of a particular antibody molecule. More than 1×10^8 different antibody specificities have been estimated to be possible. The generation of this tremendous diversity in antibody specificity occurs during B cell ontogeny in the bone marrow.[35] Within a given B cell the genes encoding the heavy and light chains of an anti body molecule are organized into specific gene segments. Thus the light chain is formed from variable (V_l), joining (J_l), and constant (C_l) gene segments that together form the variable and constant domains of the light chain. In the germ line of an undifferentiated cell are several hundred different V_l and several dozen J_l gene segments. Likewise, the heavy chain of a B lymphocyte is composed of V_H, diversity (D), and J_H segments that form the variable domain. These join to the constant region genes to form the complete heavy 9
chain molecule. Similarly, in the germ line are a large number of V_H gene segments and a smaller number of D 10
and J_H segments. During the differentiation of a B cell (Figure 1.1-5), sequential selection and rearrangement of a V_L segment with a J_L segment occurs with the accompanying deletion of intervening V_L and J_L segments (Figure 1.1-6). The rearranged VJC sequence is transcribed into mRNA and translated into the light chain. A similar sequence follows for heavy chains except that two rearrangements are necessary, a D to J_H rearrangement followed by a V_H to DJ_H rearrangement. Once rearrangement is completed, the VDJ segment is brought into proximity of the appropriate C_H segment and transcribed. Not all of the gene segment rearrangements produce functional genes. Because a B cell has two sets of heavy chain genes, one on each chromosome, and most species, including the horse, have two different sets of light chain genes,[36,37] several chances exist to form appropriate heavy and light chains. Once the heavy and light chain gene segments are recombined successfully, neither do the genes on the sister chromosome recombine nor are they expressed. This process of *allelic exclusion* ensures that the B cell produces antibodies of a single specificity. Although this random assortment of gene segments accounts for much of the diversity in antibody specificity, additional mechanisms also are involved, including *junctional diversity,* which results from the imprecise joining of gene

segments, and *somatic mutations,* which are point mutations in the hypervariable region of the heavy or light chain that occur during the proliferation of antigen-activated B lymphocytes. Such mutations appear to play a role in increasing antibody affinity for its antigen. Thus fewer than 1000 genes can give rise to more than 1 × 10^{8} molecules of the various specificities needed to recognize the vast number of antigens the host may encounter.

Figure 1.1-5 B cell differentiation. Different stages of B lymphocyte development are recognizable by expression of immunoglobulin molecules. This maturation requires a series of gene rearrangements to select the genes that will encode the antigen-binding part of the immunoglobulin molecule (variable region) and subsequently to select the genes that determine the class or subclass of the antibody molecule. Initially, immature B cells express immunoglobulin M (the majority of peripheral blood B cells), but after antigen exposure the B cell becomes activated and may express any of the immunoglobulin classes or subclasses. This determination depends largely on cytokine signals from T helper cells. Finally, activated B cells mature into short-lived antibody secreting plasma cells or become long-lived memory B cells.

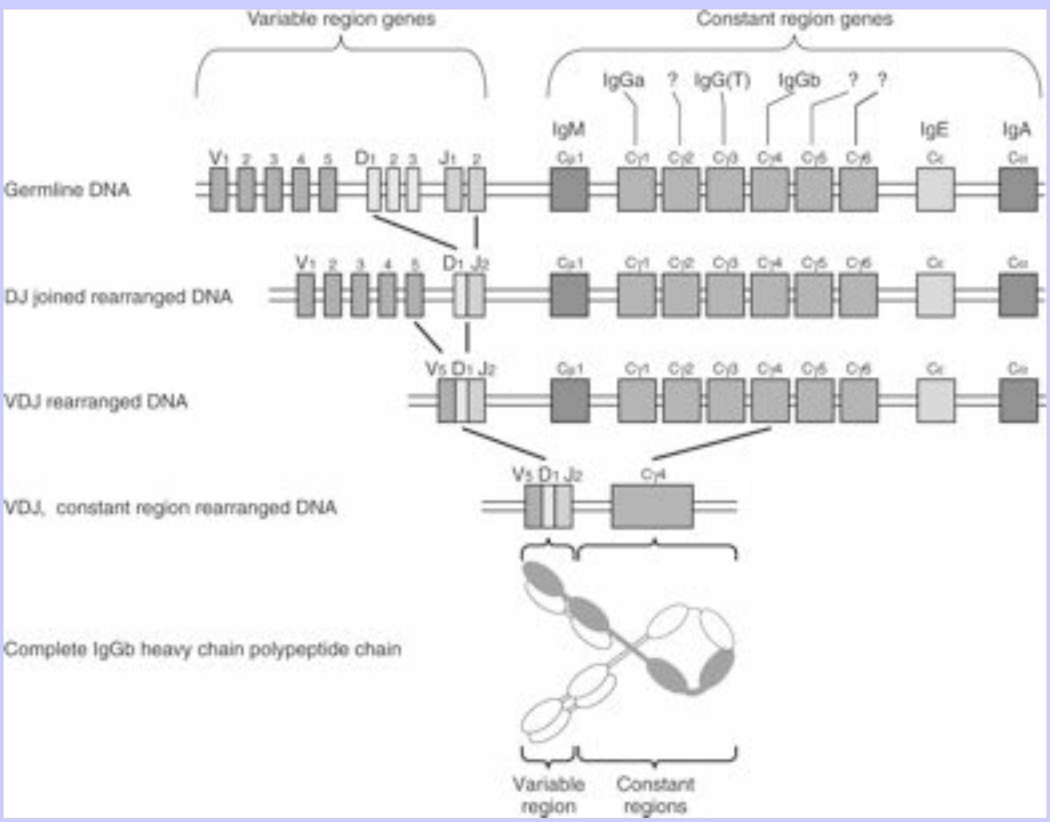


1.1.2.2 T CELL RECEPTOR AND CD3 COMPLEX: ANTIGEN-SPECIFIC RECEPTOR OF T CELLS

T lymphocytes can be differentiated from B lymphocytes in that they do not express surface immunoglobulins but instead express the T cell receptor (TCR). T cells also express another antigen called CD3. (The designation *CD* stands for *cluster designation* and resulted from an international workshop to standardize the terminology used to describe leukocyte surface antigens recognized by monoclonal antibodies.) The TCR and CD3 form a multimeric complex on the T cell surface, and this complex is involved in antigen-specific recognition.[38] The

TCR structure was first identified using antibodies that recognized a surface antigen expressed on a cloned T
lymphoma cell line. This antibody recognized a disulfide-linked heterodimer composed of an acidic (α) and a
basic (β) protein of 40,000 to 45,000 molecular weight. Similar heterodimers were found on a variety of
antigen-specific T cell lines, but not on B cells. Peptide mapping studies of the α and β chains from many differ
ent T cell lines demonstrated that they contained variable and constant domains reminiscent of immunoglobulin
structure. Further analysis indicated that like immunoglobulin genes, the TCR genes underwent gene
rearrangements during T cell development. Subsequently, two additional TCR genes were identified, the γ 10
chain and δ genes corresponding to a second heterodimer. Thus two TCRs exist, an α/β heterodimer that 11
constitutes the TCR on almost 90% of all T cells and a γ/δ-heterodimer present on approximately 10% of the
peripheral T cells. The significance of these two different TCR heterodimers has not yet been determined. One
should note that γ/δ T cells have not yet been identified in the horse. Clearly, γ/δ T cells represent a
functionally distinct populations of T cells typically associated with mucosal surfaces.[39] As such, they are
thought to play an important role in immunological surveillance.

Figure 1.1-6 Immunoglobulin gene rearrangement–somatic recombination process for production of an immunoglobulin heavy chain. The figure shows a hypothetical series of V, D, and J variable heavy chain genes, positioned 5′ to the known equine heavy chain constant region gene loci. In the first step in somatic recombination a D and a J gene segment are joined, and in the second step a V gene segment is joined to complete the VDJ recombination and form a gene capable of encoding the variable region. Subsequently, one of the six equine γ heavy chain constant regions, labeled with their corresponding immunoglublin G subclass when known, was selected to complete the gene rearrangement. Because the Cγ4 heavy chain constant region gene was selected, this leads to production of an IgGb heavy chain.



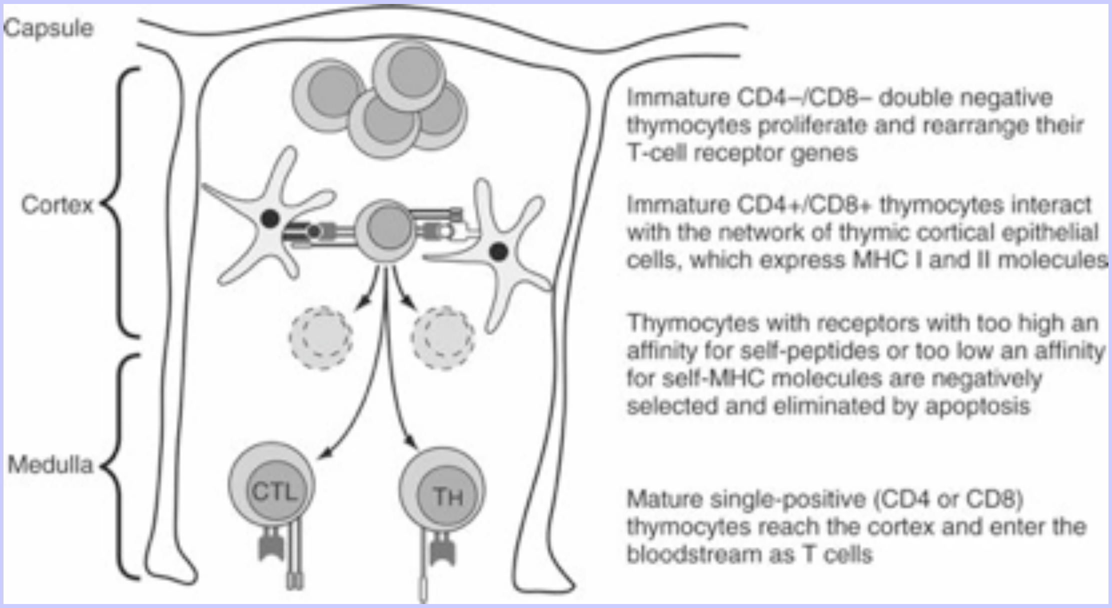
Analysis of the predicted amino acid sequences for the TCR proteins confirms a structural similarity with antibody molecules. One peculiarity in the structure of the TCR occurs in the amino acid sequence analysis. Although the α and β chains of the TCR contain a transmembrane region, both proteins have short cytoplasmic tails. That TCR itself could transmit any cytoplasmic signal in response to antigen binding therefore seems unlikely. This led to the search for other proteins associated with the TCR. Solubilization of the T cell membranes revealed that five other proteins could be immunoprecipitated with the TCR. Similar results were obtained when anti-CD3 antibodies were used. Thus the TCR heterodimer is associated noncovalently with the CD3 complex of proteins. The five proteins of the CD3 complex (γ, δ, ε, ζ, and ξ) are involved in signal transduction following TCR binding to antigen.[40] Unlike the TCR α and β proteins, the CD3 proteins have 11
large intracellular domains, some of which are phosphorylated in response to stimulation of the TCR. In 12
addition to providing a signaling mechanism for the TCR, the CD3 complex also is required for expression of the TCR heterodimer on the cell surface.[38]

The generation of diversity in the TCR during T cell ontogeny involves a mechanism that is similar to that used to generate immunoglobulin diversity. The TCR α and γ chains resemble immunoglobulin light chains in that they are composed of V, J, and C gene segments. The particular V, J, and C segments used are selected from a germ line configuration containing a few (C region) to several hundred (V region) gene segments. The selection and rearrangement of the gene segments is similar to that used by the immunoglobulin light chain and appears to involve the same recombinase. Likewise the β and δ chains resemble heavy chains, each being composed of V, D, J, and C gene segments, and their selection and rearrangement from germ line genes also parallels immunoglobulin heavy chain rearrangement. Thus the generation of diversity results from the combination of multiple gene segments and junctional diversity. However, unlike immunoglobulins, the TCR genes do not undergo somatic mutations.

1.1.2.3 T LYMPHOCYTE SUBSETS

Mature thymocytes and T lymphocytes can be divided further into two distinct populations based on their expression of the CD4 or CD8 antigen.[41] The expression of these antigens is correlated directly with the specificity of the T cell. The expression of CD4 or CD8 also correlates with the function of the T cell. Those cells that express the CD8 antigen are typically cytotoxic effector cells (cytotoxic T lymphocytes, or CTLs), whereas those that express the CD4 antigen are typically helper cells that produce cytokines to enhance antibody and cell-mediated immune responses. Although T lymphocytes in the periphery express CD4 or CD8 antigen, cortical thymocytes express both antigens. During the process of thymic selection, these cells convert to $CD4^+$ or $CD8^+$ cells or they are eliminated (Figure 1.1-7). At this stage of their development T cells are said to “learn” to recognize antigen. Also at this stage autoreactive T cells are eliminated. Although experimental studies have shown that positive and negative selection of T cells occurs, the exact mechanism of these selective processes remains unknown. Interestingly, although T cells expressing the α/β heterodimer of the TCR can be $CD4^+$ or $CD8^+$, γ/δ cells are $CD8^+$ or $CD4^-CD8^-$. These results suggest that the γ/δ cells undergo a different developmental process than α/β cells. Like the CD3 complex, CD4 and CD8 antigens are involved in the intracellular signaling event following TCR engagement with its specific antigen. Unlike B cells and antibodies that recognize antigens in solution or on cell surfaces in their native conformation, T cells only recognize *processed* antigen in association with self-molecules known as major histocompatibility complex (MHC) antigens.

Figure 1.1-7 Thymic development.



1.1.2.4 MAJOR HISTOCOMPATIBILITY ANTIGENS AND ANTIGEN PRESENTATION

The MHC originally was defined in terms of its role in allograft rejection. Following rejection of a primary allograft, antibodies that react with the allograft can be found in the recipient's sera. These antibodies can be used to identify or type tissues to determine the suitability of a donor for transplantation. Multiparous females 12
have similar antibodies in their sera because of exposure to paternal MHC antigens on the fetus.[42] Using these 13
sera, one can identify a large number of serologically defined transplantation antigens. Genetic analysis of the MHC region demonstrates that a number of closely linked genes encode several different, though related, antigens that are involved in allograft rejection. These closely related genes are referred to collectively as MHC I genes and their products as MHC I antigens. In addition to the serologically defined MHC I antigens, another group of antigens was identified within the MHC that are involved in the stimulation of mixed lymphocyte responses and the control of immune responsiveness. These MHC II antigens are structurally and functionally distinct from the MHC I antigens, except that both are involved in T cell recognition of antigen.

MHC I antigens are cell surface glycoproteins consisting of two noncovalently associated proteins, an MHC-encoded transmembrane protein of approximately 44-kd (α chain) and a β_2-microglobulin, a 12-kd protein encoded outside of the MHC.[43] MHC I antigens are expressed on the surface of most nucleated cells. The highest level of expression is on lymphoid cells, with lower expression on fibroblasts, muscle cells, and neural cells. MHC I antigens are not detectable on early embryonal cells, placental cells, and some carcinomata. The level of expression of MHC I antigen can be modified by treatment with cytokines or infection with viruses. Interferons and TNF-α augment MHC I antigen expression. This augmented expression results from increased production of MHC I mRNA. The regulatory region of the MHC I antigen genes contains interferon and TNF-α responsive elements that control the transcriptional activity of these genes.

The MHC I region of most animal species, including the horse, contains a number of MHC I α chain genes, some of which are pseudogenes and are not expressed.[44] In the horse these genes are located on chromosome 20, and those genes that are expressed exhibit a great deal of polymorphism.[45,46] Much of this polymorphism is localized in the α_1 and α_2 domains, the α_3 domain being more conserved. The polymorphism of these two domains is related to their role in presenting antigen to T cells.

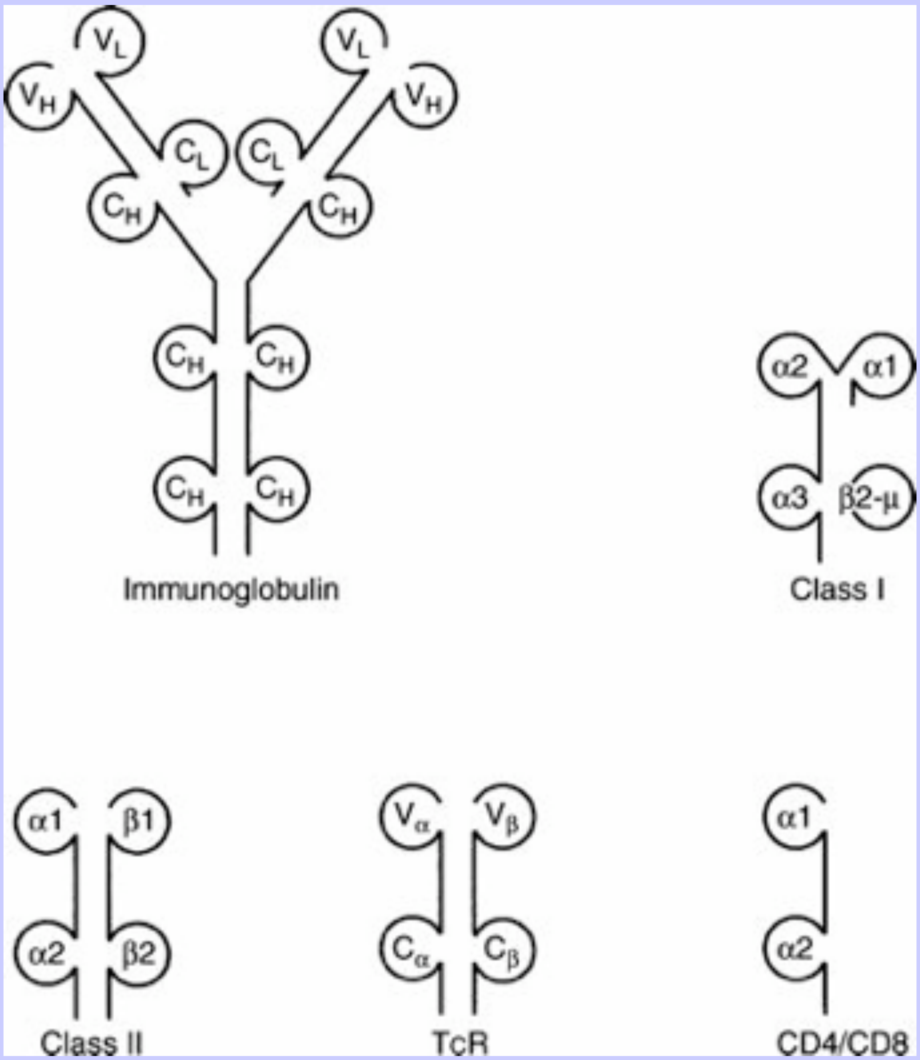
The physiologic role of MHC I antigens was defined when cytotoxic T cell (CTL) lysis of virus infected cells was discovered to be restricted to target cells expressing the same MHC I antigen as the CTL.[47] This observation led to the realization that T cells recognize the combination of self-MHC and foreign antigen. Furthermore, those T cells that recognize MHC I antigens invariably express the CD8 co-receptor. The nature of the association between MHC I and the foreign antigen remained unclear until x-ray crystallographic studies of human MHC I antigen were performed. In addition to revealing the structural organization of the domains of the MHC I antigen, the image also revealed a cleft that lay between the α_1 and α_2 domains. Researchers proposed that this cleft binds the processed peptide epitopes for presentation to the T cell receptor. Indeed, the cleft of the crystallized protein used for x-ray diffraction studies contained a contaminating peptide.[48] Other experiments showed that the incubation of cells with purified viral peptides resulted in the lysis of the cells by virus-specific, MHC I–restricted CTLs. Together these results support the notion that *endogenous processing* of viral antigens leads to the association of the viral peptides with MHC I antigens on the surface of the infected cell, and this is recognized by the TCR-CD3 complex in association with CD8.[49] These viral antigens get to the cell surface by a peptide transport system the function of which is to transport processed peptides from the cytosol to the endoplasmic reticulum.[50] Once in this compartment, peptides are handed off to newly formed MHC class I molecules and they stabilize a trimolecular complex with β_2-microglobulin. This complex is transported to the cell surface, where antigen presentation occurs. Because this is a normal cellular process for eliminating degraded proteins from the cell, MHC I antigens are normally loaded with these self-peptides. Indeed, this encounter with MHC I loaded with self-peptides in the thymus is responsible for the deletion of autoreactive clones during T cell ontogeny.

MHC II antigens are heterodimeric, transmembrane glycoproteins composed of an acidic α chain (25 to 35 kd) and a basic β chain (25 to 30 kd).[51] A third chain, the invariant chain, is associated with the MHC II antigen during assembly in the endoplasmic reticulum but is not expressed on the cell surface. The α and β polypeptides are encoded within the MHC region. Both polypeptides possess two extracellular domains. The α chain has a single disulfide bond located in its membrane proximal (α_2) domain, whereas the β chain has a disulfide bond in both of its extracellular domains. Structurally, MHC II antigens resemble MHC I antigens and are also members of the immunoglobulin superfamily, a group of proteins with structural similarities to immunoglobulin molecules (Figure 1.1-8).[52]

The MHC II genes are functionally and structurally distinct from the MHC I genes. Unlike MHC I antigens, the MHC II antigens are restricted in their expression to certain cells of the immune system: B lymphocytes, dendritic cells, macrophages, and activated T lymphocytes of some species. Other cells may express MHC II antigens after treatment with various cytokines.[53–55] Interferon-γ, TNF-α, 1,25-dihydroxyvitamin D_3, and granulocyte-macrophage colony-stimulating factor can induce MHC II antigen expression on monocytes, macrophages, and other cells. IL-4 enhances MHC II antigen on B cells. A number of agents have been shown 13
to downregulate MHC II antigen expression including glucocorticoids, prostaglandins, and α-fetoprotein. 14
Although MHC II antigen expression also is regulated at the transcriptional level, no interferon or TNF-α response elements have been identified in the regulatory regions of MHC II genes. In fact, the regulatory region

of MHC I and MHC II genes are different, and this fact is probably responsible for the differences in tissue distribution for these antigens.[43]

Figure 1.1-8 The immunoglobulin superfamily. Immunoglobulin serves as the prototype model for the superfamily. The heavy and light chains of an immunoglobulin molecule can be divided into variable (V_H and V_L) and constant domains (C_H and C_L). Analogous regions have been identified on a variety of other molecules involved in immune recognition including class I and II antigens, the T cell antigen receptor *(TCR),* and the CD4 and CD8 antigens found on T cells (see text). Disulfide bonds forming the domains are not shown.



Like the MHC I genes, the MHC II region contains genes for multiple MHC II antigens, some of which appear to be pseudogenes and are not expressed. Those α and β chains that are expressed exhibit a high degree of allelic variability, though typically the β chain exhibits the most polymorphism. Unlike the MHC I genes the variability in the MHC II genes results from point mutations. Correspondingly, less polymorphism occurs in the MHC II genes compared with the MHC I genes. The MHC II region of other species, including the horse, have been studied using human DNA probes and extensive polymorphism involving several genes has been identified.

Although antigens processed via the endogenous pathway are associated with MHC I antigens, antigen processed via the *exogenous pathway* is associated with MHC II antigens (Figure 1.1-9).[49] Endocytosed antigen, such as that phagocytosed by a macrophage, is partially degraded in a prelysosomal compartment of low pH and limited proteolytic activity. The processed protein associates with a peptide binding site at the junction of the α_1 and β_1 domains of the MHC II molecule. This association of the epitope with the MHC II molecule protects it from further degradation. The MHC II molecule then is reexpressed on the cell surface for subsequent presentation to the T cell. The immune system contains a distinct group of antigen-presenting cells called dendritic cells that are specialized to capture antigens and initiate T cell immunity. They move freely from epithelial surfaces to adjoining lymph nodes.[56] Dendritic cells can be found in a variety of locations in the body and often are named based on their microscopic appearance. Hence interdigitating cells found in lymph nodes, veiled cells in lymphatics, and Langerhan's cells in skin are dendritic cells. Immature dendritic cells can take up antigens by micropinocytosis using their extensive cellular processes or receptor-mediated phagocytosis. This results in activation and migration to a regional lymph node where antigen presentation to T lymphocytes occurs. Mature dendritic cells have high levels of MHC II expression on their surface and are no longer phagocytic but are efficient stimulators of MHC I- and MHC II-restricted T cell responses in the draining lymph node (Figure 1.1-10).

In a complex immunogen, certain antigenic determinants are particularly effective at stimulating an antibody response. These *immunodominant* epitopes often are located at exposed areas of the antigen such as in polypeptide loops. These types of structures often are mobile and may allow for easier access to the antibody binding site. T cell epitopes possess a particular structural characteristic resulting in the formation of amiphipathic helices. However, structure alone does not determine the immunogenicity of a particular antigen. T cell recognition of foreign antigen requires more than just the expression of the processed antigen on the surface of the antigen presenting cell. Additional signals provided by the antigen presenting cell are required for the activation of the T lymphocytes. Among these are signals provided by other accessory molecules found on the antigen presenting cell and various cytokines present in the extracellular environment.

1.1.2.5 SIGNALING THROUGH THE ANTIGEN-SPECIFIC RECEPTORS

The encounter of specific antigen by a T cell or a B cell antigen-specific receptor results in an intracellular 14
signaling cascade that eventually leads to the production of various proteins and the proliferation of the 15
stimulated cell. T cell recognition of antigen involves the engagement of a TCR-CD3-CD4 or TCR-CD3-CD8 complex with processed peptide in cleft of an MHC II or MHC I molecule (Figure 1.1-11).[57] The engagement of the TCR-CD3 complex with the appropriate MHC antigen–containing peptide results in the binding of CD4 or CD8, depending on the MHC antigen, with the TCR-CD3 complex. In doing so, the *lck* protein—tyrosine kinase, which is associated with the cytoplasmic tail of CD4/CD8—phosphorylates the cytoplasm of the CD3 proteins in regions known as *immunoreceptor tyrosine-based activation motifs* (Figure 1.1-12). These motifs serve as docking sites for other kinases including ZAP70 and *fyn*. Recruitment of ZAP70 to CD3 results in its

subsequent phosphorylation and activation by *lck*. Once activated, the ZAP70 subsequently can phosphorylate other signal proteins including phospholipase C. Activation of phospholipase C leads to the cleavage of phosphatidylinositol bisphosphate into inositol 3-phosphate (IP_3) and diacylglycerol. IP_3 and diacylglycerol are second messengers. IP_3 causes release of stored Ca^{2+} from the endoplasmic reticulum; diacylglycerol activates protein kinase C. The increase in intracellular Ca^{2+} levels and activation of protein kinase C leads to phosphorylation of various transcriptional factors. These transcriptional factors regulate the expression of the genes for various cytokines and their receptors (Figure 1.1-13). The process subsequently is downregulated by various phosphatases that are recruited to and subsequently dephosphorylate the CD3 immunoreceptor 15
tyrosine-based activation motifs. A similar process occurs in B cells when the surface immunoglobulin receptor 16
is cross-linked on binding to specific antigen.

Figure 1.1-9 Antigen processing pathways. This figure depicts major histocompatibility complex I (MHC I) antigen presentation to the left of the diagram, and MHC II antigen presentation to the right. In MHC I antigen presentation, *(a)* peptides generated by degradation of proteins in the cytoplasm are transported into the endoplasmic reticulum *(b)*. In this location MHC I molecules bound by the membrane protein calnexin bind the peptides, which allows release of the MHC I molecules by the calnexin and transport through the Golgi complex to the cell surface (*c*). In MHC II antigen presentation, antigen is taken up by phagocytosis *(1)* into the endosome compartment and routed to lysosomses for degradation. Vesicles containing MHC II molecules produced in the endoplasmic reticulum fuse with the endosomes *(2),* and the MHC II molecules bind with the degraded peptides for transport back to the cell surface *(3)*. The MHC II molecules are prevented from binding the endogenous peptides in the endoplasmic reticulum by the presence of invariant chain that is only lost in the acidic endosomal environment.

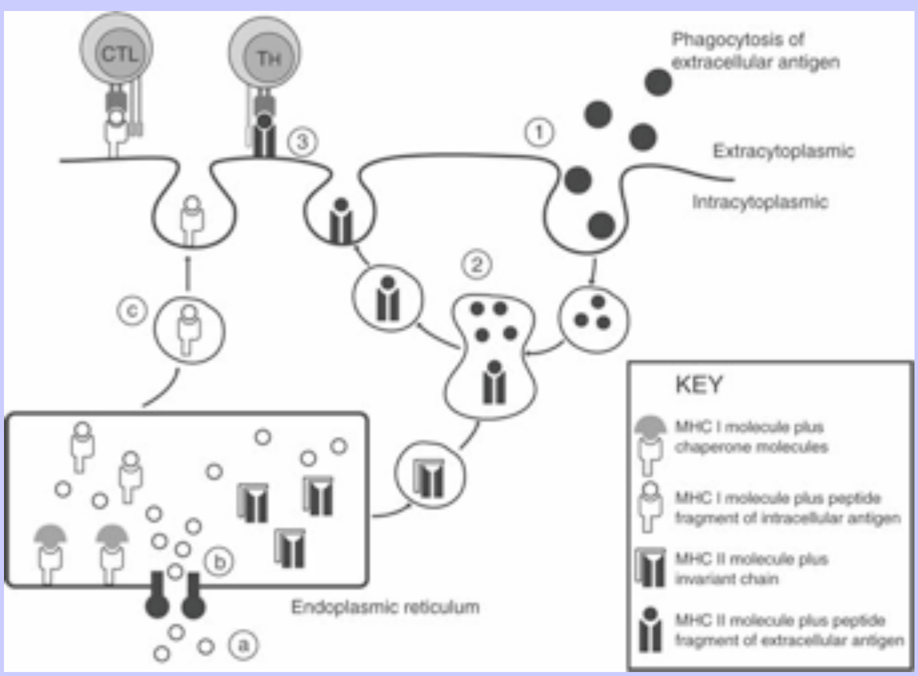


Figure 1.1-10 The role of professional antigen-presenting cells. In this figure, pathogen invasion is followed by antigen uptake by a dendritic cell, the most potent of the antigen-presenting cell family. The dendritic cells become activated and migrate to a local lymph node where they are effective at stimluating naïve T cells, including T helper cells and cytotoxic T lymphocytes.

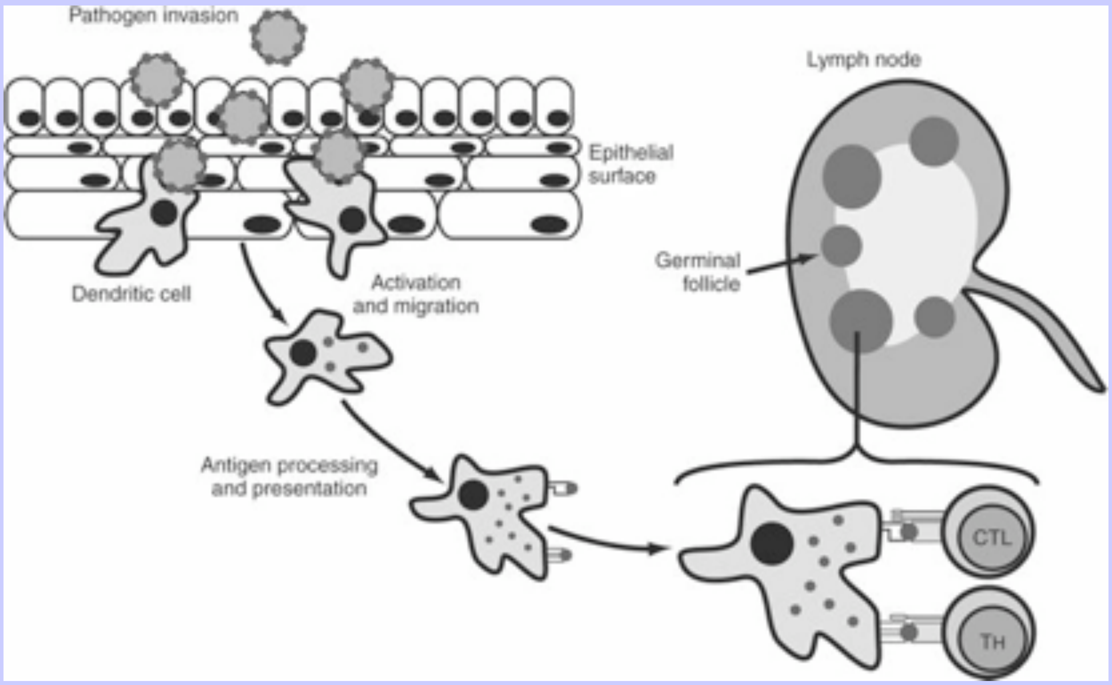

Figure 1.1-11 Class I and II restricted T cell recognition: the role of T cell CD4 and CD8 molecules. T cells use their T cell receptors to recognize processed antigen presented in combination with major histocompatibility complex molecules I or II. T cells exclusively express CD4 (T helper cells) or CD8 (cytotoxic T lymphocytes). The CD4 molecule is required for interaction with MHC II molecules, whereas CD8 is required for interaction with MHC I. As a result, T helper cells recognize antigen presented by MHC II molecules, and cytotoxic T lymphocytes only recognize antigen presented by MHC I molecules.

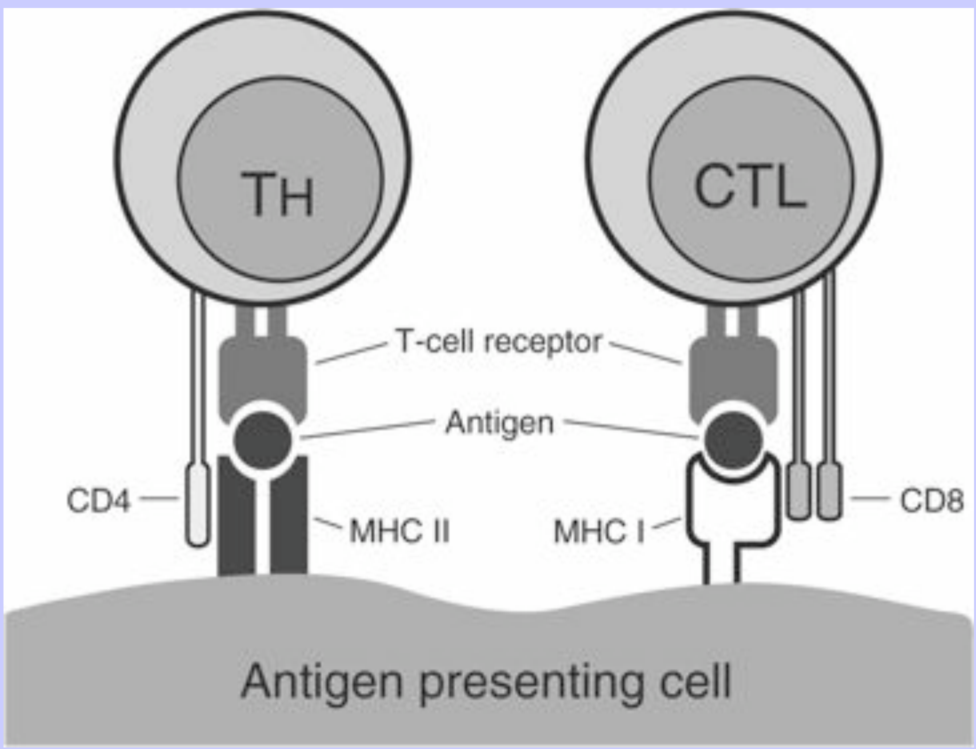


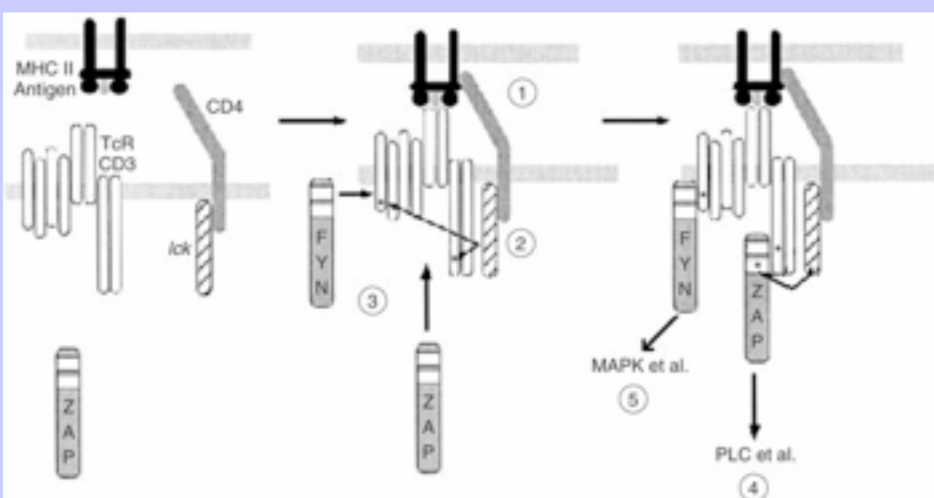
1.1.2.6

CO-STIMULATORY SIGNALS

In addition to the interaction of TCR-CD3 and CD4/CD8, other cell surface antigens are involved in the signaling pathways.[58] Of greatest importance is the interaction of CD28 on the T cell with B7 on the antigen presenting cell. In the absence of CD28/B7 co-stimulation, T cells are rendered functionally inactive or anergic. On restimulation, these anergic T cells fail to proliferate or produce cytokines such as IL-2. The induction of anergy can be prevented by the addition of exogenous IL-2 or, more importantly, by interaction of the CD28 cell surface antigen with its ligands, B7-1(CD80) and B7-2(CD86). Stimulation of CD28 appears to be

necessary for subsequent intracellular signaling events following TCR stimulation. CD28 cross-linking enhances various biochemical events triggered by TCR-mediated signaling, including the activation of phospholipase C, *lck,* and Raf-1 kinase, as well as inducing the influx of Ca^{2+} and generation of phosphoinositides. Other molecules including the TNF-receptor family member CD40 also have been shown to 16
regulate T cell growth or cell death. The engagement of CD40 on the T cell with its ligand, CD40L, on the 17
antigen presenting cell leads to NF-κB activation and promotes cell survival and cell cycle progression. The binding of other members of this family, notably TNF-α, to their receptor on activated T cells typically results in the activation of a biochemical cascade of caspases that lead to apoptosis. The cytocidal activity of these receptors results from the death effector domains within the intracytoplasmic portion of the receptor. By contrast, CD40 lacks intracellular death domains and instead has amino acid motifs that bind TNF-R–associated factors and promote NF-κB activation. In addition to their role in promoting T cell activation and growth, the CD28/B7 and TNF-receptor pathways also may play a dominant role in the induction of specific T helper cell subsets.

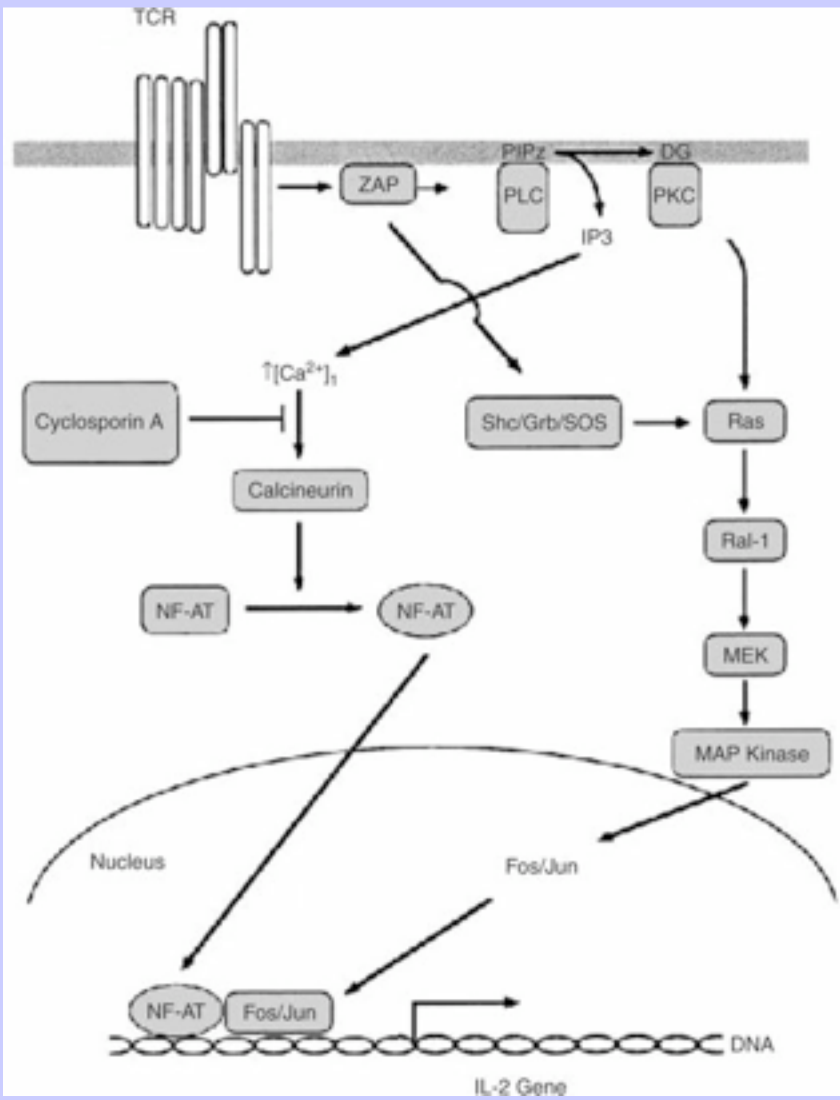
Figure 1.1-12 Intracellular signaling by the T cell–CD3 receptor. T cell receptor recognition of its specific peptide in the peptide-binding groove of a major histocompatibility complex molecule on an antigen-presenting cell results in the attraction of CD4/CD8 to the complex *(1)* and the phosphorylation of CD3 proteins by *lck* associated with CD4/CD8 *(2)*. The phosphorylation of these sites (*) on CD3 leads to the attraction and binding of other kinases (*fyn* and ZAP70) to CD3, where they in turn are phosphorylated and activated *(3)*. Activation of ZAP70 leads to the subsequent activation of phospholipase C *(4)*. Activation of *fyn* ultimately leads to the mitogen-activated protein (MAP) kinases pathway and cell division *(5)* (see also Figure 1.1-13).



1.1.3 Cytokines, Cytokine Receptors, and T Helper Cell Subsets

Frequent mention has been made in this chapter of the role of cytokines in regulating immune responses. Indeed, this particular area of immunology has grown tremendously over the past several years. This rapid acquisition of knowledge results from the application of modern molecular biology techniques to the identification and characterization of specific cytokines. Initial studies of the role of soluble factors in the regulation of immune responses often were confounded by the heterogeneous nature of the culture supernatants used as the source of the cytokine activity. Furthermore, using biologic assays to identify specific cytokines resulted in the practice of assigning descriptive names to newly discovered cytokines (lymphocyte activating factor, T cell growth factor, etc.).[59] Such naming quickly led to confusion because individual cytokines often exhibited multiple biologic activities and biologic assays were not specific for a particular cytokine. Once the genes for the cytokines had been cloned and the resulting proteins identified, eliminating much of the confusion was possible. The adoption of the interleukin terminology for naming cloned immunoregulatory cytokines has clarified further the biologic function and role of particular cytokines.[60] After the gene for a new cytokine is identified and the biologic activity of the purified protein is characterized, the gene is assigned an interleukin designation. To date, more than 50 different cytokines and chemokines have been cloned, sequenced, and synthesized in bacterial and eukaryotic expression systems. This work has led to a better understanding of cytokine function and to their use in a variety of clinical settings. Table 1.1-5 contains a list of interleukins and their known biological activity. Not all 17
cytokines have been given interleukin designation. Interferons, certain growth fac tors (platelet derived growth 18
factor, TGF-β), and TNF-α have retained their original names. That other cells besides T cells produce cytokines and interleukins also should be emphasized. For example, monocytes and macrophages are the major source of IL-1, IL-6, and TNF-α. Thus the term *lymphokine* that was used originally to describe immunoregulatory products of lymphocytes has been replaced with *cytokine,* which denotes the more varied sources of immunoregulatory molecules.

Figure 1.1-13 Intracellular signaling pathway. After activation of ZAP70 and other receptor-associated kinases, a propagation of the signal occurs as subsequent kinases and target proteins are phosphorylated. Increases in intracellular Ca^{2+} leads to the activation of calcineurin, which is necessary for NF-AT activation. This step is the target for cyclosporin A, a potent and specific immunosuppressive agent. Activation of the transcriptional factors NF-AT and *fos/jun* leads to their translocation into the nucleus and the binding to regulatory DNA sequences upstream of the promoter for the interleukin-2 gene.



Many cytokines have similar structures and can be grouped into like families. Helical cytokines have α helices as the predominant structure. IL-2 serves as the prototypical cytokine for this family (Figure 1.1-14). This family can be divided further into two subclasses based on the length of the helices: long helical (many growth factors including IL-3 and IL-7) and short helical (IL-2, IL-4, and IL-13). IL-1 is a β-trefoil cytokine with 12 antiparallel 18
β strands forming a bowl-like structure. Most chemokines and other smaller cytokines contain α helices and β 19
sheets, typically a single α helix and more than two β sheets. TNF-α is the prototype for the β-sandwich family the structure of which characteristically consists of five antiparallel strands with an overall jelly roll structure.

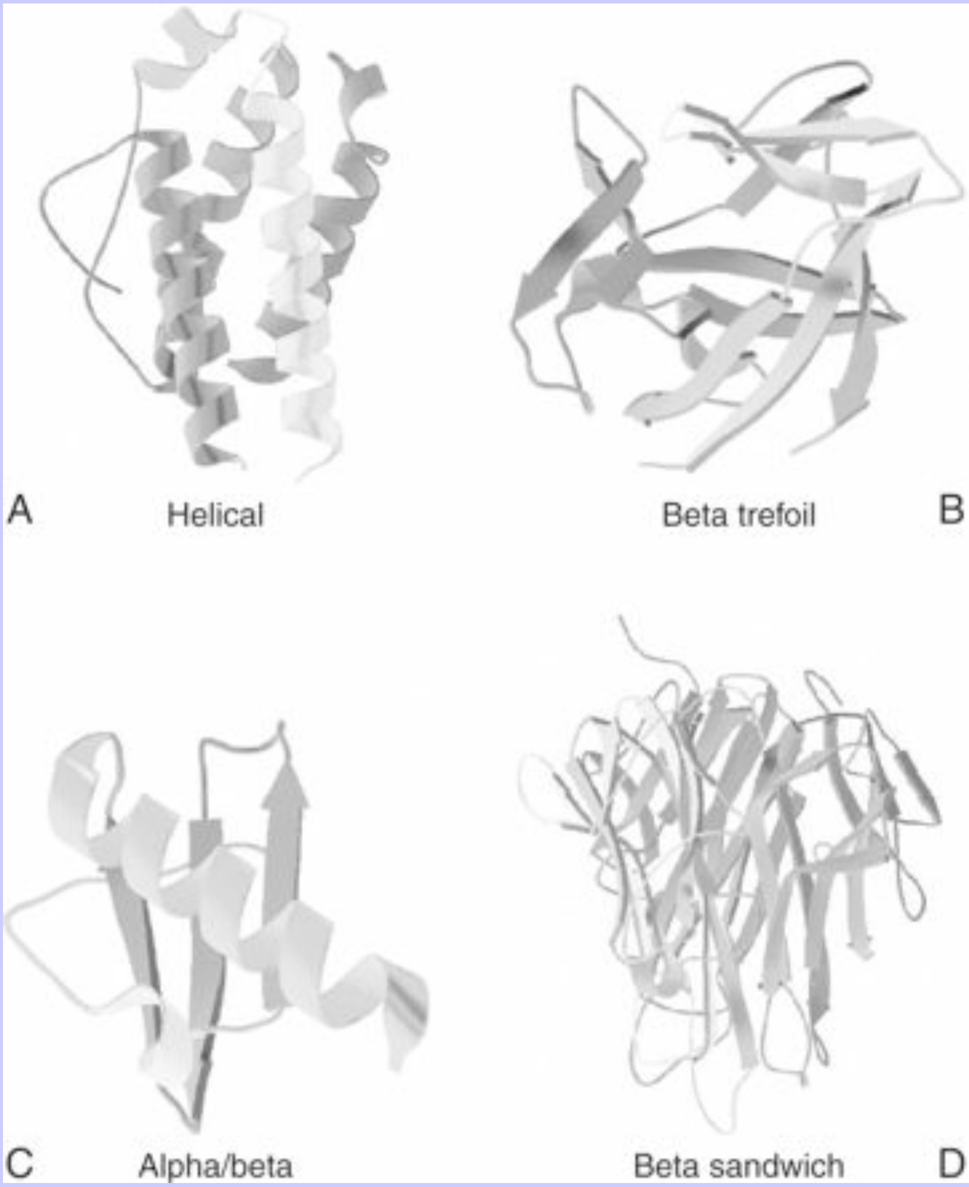
TABLE 1.1-5 Interleukins

INTERLEUKIN	BIOLOGIC ACTIVITIES AND SOURCE
1	Lymphocyte-activating factor. Enhances multiple biological activities affecting a variety of lymphoid and nonlymphoid cells.
2	T cell growth factor. Provides proliferative signal for T cells. Also affects B cells, macrophages, and natural killer cells. High concentrations of IL-2 stimulate cytolytic activity in natural killer cells and T cells. Produced by activated type 1 T helper cells and some $CD8^+$ cells.
3	Multi–colony-stimulating factor. Promotes the growth of various hematopoietic cell precursors. Produced by T cells and myelomonocytic cell lines.
4	B cell stimulatory factor 1. Stimulates growth, maturation, and differentiation of B cells. Also provides proliferative and differentiation signal for some T cells. Produced by type 2 T helper cells.
5	T cell replacing factor. Stimulates B cell proliferation and immunoglobulin synthesis. Also stimulates T cell proliferation and differentiation, as well as eosinophil formation in the bone marrow. Produced by type 2 T helper cells.
6	B cell differentiation factor. Promotes maturation and immunoglobulin production by B cells. Stimulates T cell growth and IL-2 synthesis. Induces the production of acute phase proteins by hepatocytes. Produced by macrophages, T cells, stromal cells, fibroblasts, and a variety of other cell lines.
7	Pre-B cell growth factor. Stimulates proliferation and maturation of early B and T cells as well as mature T cells. Produced by stromal cells derived from bone marrow.
8	Neutrophil chemokine. Produced by monocytes and hepatocytes.
9	Also known as P40. Supports the growth of certain T cell clones. Produced by $CD4^+$ T cells.
10	Cytokine synthesis inhibitory factor. Inhibits the production of IL-2 and interferon-γ by type 1 T helper cells. Produced by type 2 T helper cells.
11	An IL-6–like factor produced by bone marrow stromal cells.
12	Natural killer cell differentiation factor. Augments natural killer cell function and stimulates generation of type 1 T helper cells. Produced by macrophages.
13	Produced by type 2 T helper cells. Downregulates cytokine production by macrophages/monocytes while activating B cells.
14	A high-molecular-weight B cell growth factor produced by T cells and some B cell lines.
15	A T cell growth factor similar in function to IL-2.
16	Chemokine for $CD4^+$ T cell subset. Produced by T cells, mast cells, and eosinophils.
17	A family of related cytokines. Enhances expression of the intracellular adhesion molecule 1 on fibroblasts. Also stimulates epithelial, endothelial, or fibroblastic cells to secrete IL-6, IL-8, granulocyte colony-stimulating factor, and prostaglanding E_2.
18	An inducer of interferon-γ production by T-cells.

19	A homolog of IL-10.
20	An autocrine factor for keratinocytes that regulates their participation in inflammation.
21	Stimulates proliferation of B cell by cross-linking of the CD40 antigen, bone marrow progenitor cells, and naïve T cells.
22	A proinflammatory cytokine. Increases the production of acute phase proteins.
23	Produced by dendritic cells. Stimulates the production of interferon-γ by T cells.
24	Selectively suppresses the growth of tumor cells by promoting cell death by apoptosis.
25	Produced by stromal cells. Supports proliferation of cells in the lymphoid lineage.
26	Induces the expression of IL-6, IL-8, and intracellular adhesion molecule 1 in primary bronchial epithelial cells.
27	Similar to IL-17. Expressed in the brain.

The availability of cloned cytokines has permitted the identification and characterization of cytokine-specific receptors. Cytokine receptors also can be grouped into major families: class I or class II receptor families, immunoglobulin superfamily receptors, the TNF receptor family and Toll-like receptors (IL-1 and IL-18).[61] The best characterized of these is the class I receptor for IL-2, which is composed of three subunits; α, β, and γ. Although the α and β subunits are involved in the specific binding to IL-2, the γ chain is involved in signal transduction after IL-2 is attached to the receptor. Five different immunologically important cytokines share this common cytokine receptor γ chain, though each has its own unique α or αβ binding subunits (Figure 1.1-15). Other common signaling chains of this type of receptor include βc (IL-3, IL-5, and granulocyte-macrophage colony-stimulating factor) and gp130 (IL-6 and IL-11). Class II receptors are illustrated by the interferons with receptors that consist of at least two chains. In contrast to the chains being denoted α and β analogous to the nomenclature for type I cytokine receptors, the chains are called IFNAR-1 and IFNAR-2 for α/β interferons and IFNGR-1 and IFNGR-2 for interferon-γ. A third receptor, CRF2-4 is a component of the IL-10 receptor. The TNF receptor family is composed of two separate receptors, TNF-RI and TNF-RII. Although both can bind TNF, no 19
structural homology is found in their intracellular domains, indicating that they signal by distinct mechanisms. 20
TNF-RI is thought to be the main signaling receptor because many biological actions of TNF, including cytotoxicity, fibroblast proliferation, and the activation of NF-κB, can be elicited in the absence of TNF-RII. The IL-1 receptor is a member of the Toll-like receptor family. This receptor superfamily represents an ancient signaling system that was identified initially in *Drosophila melanogaster*. The introduction of a pathogen into *Drosophila* leads to the activation of proteases that cleave a precursor and generate an extracellular ligand of a receptor called Toll, the intracellular part of which is homologous to the IL-1 receptor cytoplasmic tail. Other Toll-like receptors are involved in other signaling pathways in innate immune and inflammatory responses, indicating this receptor superfamily represents an ancient signaling system.[62]

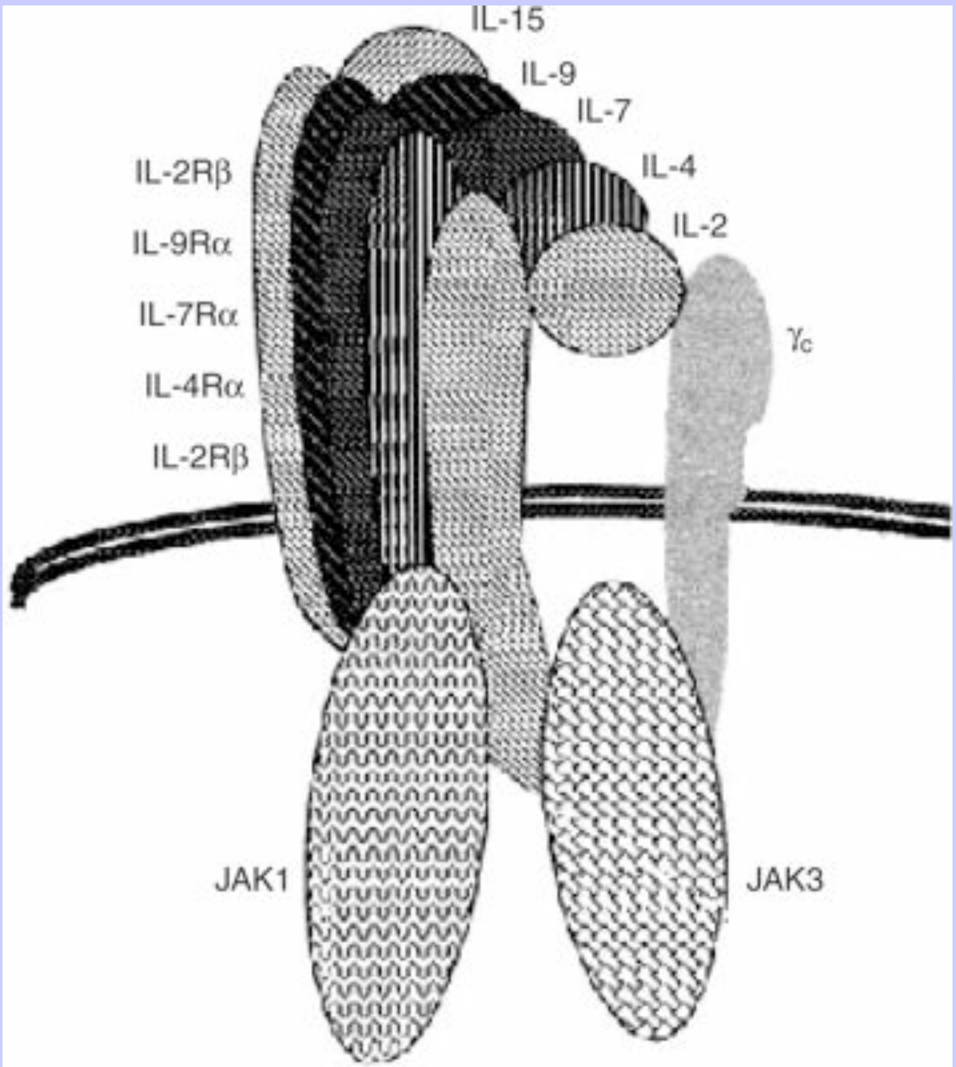
Figure 1.1-14 Cytokine structural families. **A,** Helical cytokine. **B,** β-Trefoil. **C,** α/β. **D,** β sandwich.



A common feature of all receptor families is that signaling is initiated through the recruitment of protein tyrosine kinases and other cytosolic proteins to the receptor.[63,64] Although most cytokine receptors lack intrinsic kinase activity, they do have a family of Janus protein tyrosine kinases (JAKs) associated with their cytoplasmic tails. Following binding of a ligand to its cognate receptor, receptor-associated JAKs are activated. A family of transcriptional factors known as STATs (signal transducers and activators of transcription) in turn are activated by tyrosine phosphorylation by the activated JAKs, allowing the STAT to dimerize (Table 1.1-6). After dimerization, the STAT translocates into the nucleus and binds to the DNA sequence it recognizes via a DNA-binding domain

on the protein. The binding of the STAT protein to the DNA subsequently modulates gene expression. The sharing of receptor subunits combined with a similar sharing of JAKs and STATs accounts for similar biological functions of many cytokines (see Table 1.1-5).

Figure 1.1-15 Type I cytokine receptors. These receptors are characterized by cytokine-specific α and β chains involved in ligand binding and a shared or common γ chain used for intracellular signaling. The Janus kinases *(JAK)* are associated with the cytoplasmic tails of these receptors and are responsible for signal transmission (see Table 1.1-6).



In addition to the JAKs and STATs, other transcriptional factors can activate multiple genes involved in inflammatory responses and apoptosis. One of these transcriptional factors, NF-κB, regulates many

proinflammatory cytokines including TNF-α, IL-1, and IL-8. NF-κB itself is activated by a number of cytokine receptor signaling cascades including TNF receptors.[65] In the cytoplasm, NF-κB is associated with an inhibitory protein, IκB, which prevents its translocation to the nucleus. Phosphorylation of IκB leads to its degradation and the translocation of NF-κB to the nucleus, where it binds to its corresponding DNA motif, altering gene transcription. NF-κB activation also is associated with resistance to apoptosis, probably as the result of its effect 20
on IL-8 transcription because this chemokine is antiapoptopic.[66] Increased levels of IL-8 in inflammatory lung 21
lesions and the increase in NF-κB activation likely accounts for the neutrophil accumulation observed in some forms of human asthma[67] and equine recurrent airway obstruction.[68]

TABLE 1.1-6 Cytokines and the JAKs and STATs They Activate[*]

CYTOKINE	JAKs	STATs
Interferon-α/β	JAK1, Tyk2	STAT1, STAT2
Interferon-γ	JAK1, JAK2	STAT1
Interleukin-10	JAK1, Tyk2	STAT3
Interleukin-12	JAK2, Tyk2	STAT3, STAT4
Granulocyte colony-stimulating factor	JAK1, JAK2	STAT3
γC	JAK1, JAK3	STAT5A, STAT5B, STAT3
Interleukin-4		STAT6
Interleukin-13		STAT6
bc	JAK2, JAK1	STAT5A, STAT5B
gp130	JAK1, JAK2, Tyk2	STAT3

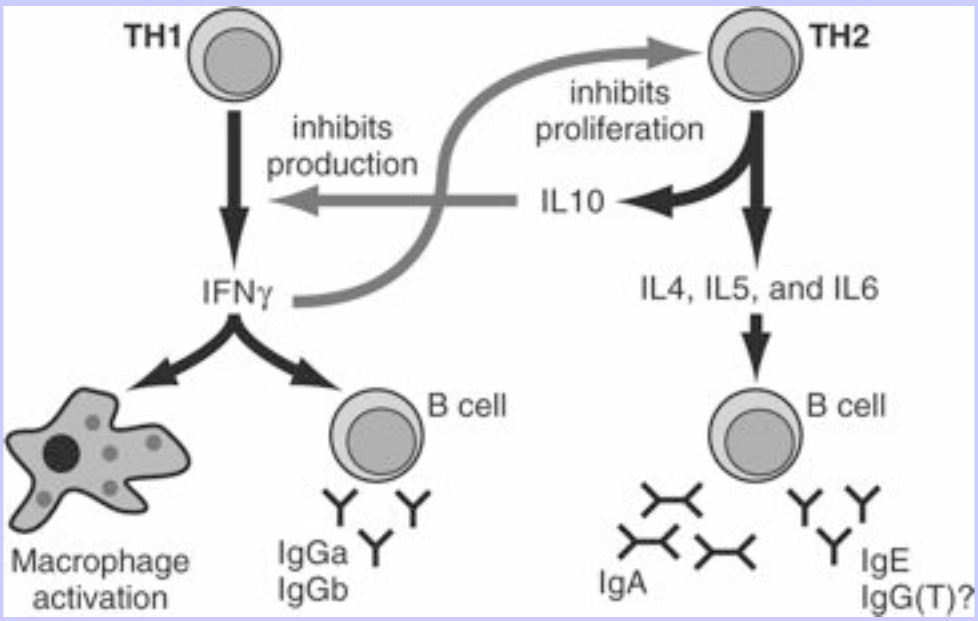
* *JAK,* Janus protein tyrosine kinase; *STAT*, signal transducer and activator of transcription.

1.1.3.1 IMMUNOREGULATION

The generation of an immune response requires the interaction of multiple leukocyte subsets including macrophages, dendritic cells, B cells, and $CD4^+$ and $CD8^+$ T cells. Although the initial interactions of the B and T cells involve recognition of specific epitopes, which in the case of the T cell are presented in the context of MHC antigens, cytokines produced by the various cells mediate subsequent interactions. Although macrophages, B cells, and even nonhematopoietic cells produce a variety of cytokines with immunoregulatory activity, the T helper cell plays a central role in regulating immune responses. Much effort over the past decade has focused on the characterization of helper T cells and the soluble factors they produce. What is apparent now is that $CD4^+$ helper cells may be divided further into distinct helper cell subsets based on the cytokines they produce (Figure 1.1-16). T helper type 1 (TH1) cells produce interferon-γ and IL-2, cytokines involved in the induction of cell-mediated immune responses. TH2 cells produce IL-4, IL-13, and IL-5, cytokines involved in the induction of antibody responses. The best evidence for separate T helper cell populations comes from the study of intracellular parasite infections in mice. Those strains of mice resistant to *Listeria donovani* infection develop a cell-mediated immune response characterized by activated macrophages and TH1 cells. By contrast, the susceptible BALB/c strain of mice generates a vigorous antibody response and TH2 helper cells. TH1 cells also have been implicated in various autoimmune diseases characterized by the induction of self-reactive

cytotoxic cells. TH2 cells play a central role in resistance to extracellular parasites such as intestinal helminths and in induction of allergic diseases. A similar contribution of TH1 and TH2 responses in protective and pathologic responses in the horse have been described.[69,70]

Figure 1.1-16 T helper cell types 1 and 2 regulation. The TH1 lymphocyte subsets provide help for macrophage activation, cytolytic activity, and production of a subset of immunoglobulin G subclasses. The TH2 promotes antibody responses, including IgA, IgE, and the remainder of the IgG subclasses. The response is mediated by production of cytokines that have a regulatory effect on one another.



Although what determines whether a helper cell will be a TH1 or TH2 cell is unclear, one proposal is that the initial encounter with the antigen during the innate immune response may determine the fate of the helper cell. Multiple factors probably are involved in this process; however, the single most important factor is the type and amounts of cytokines present at the time of the initial encounter with the antigen. Among the cytokines that may play a role, IL-12 and interferon-γ are the main inducers of TH1 responses, and IL-4 and IL-10 play a similar role for TH2 responses. IL-12, produced by macrophages and dendritic cells, is a potent inducer of interferon-γ that inhibits TH2 cell induction. The evidence from a variety of models to date suggests that IL-12 is the single most important factor in regulating the differentiation and magnitude of the TH1 response; however, this should not preclude the possibility that additional factors, such as IL-18, may have an equally important role in regulating TH1 responses in some situations. What is also apparent is that IL-4 plays a similar, crucial role in the induction of TH2 immune responses. IL-4 production by mast cells and IL-10 production by macrophages favors TH2 development in part by inhibiting TH1 cells. Other signals (e.g., PGE_2)

can induce differentiation of potent antigen-presenting cells with dendritic morphology that produce low levels of IL-12 and high levels of IL-10 preferentially inducing TH2 differentiation. 21

22

In addition to cytokines, another influence on T helper cell differentiation is the interaction of the B7/CD28 and CD40/CD40L co-stimulatory pathways. In particular, these co-stimulatory pathways may regulate the differentiation of TH1 and TH2 cells by affecting the intensity and the strength of signals through the CD3/TCR complex and those provided through the co-stimulators. High-intensity stimulation favors TH2 development, whereas lower-intensity signals favor TH1 cells. The association of stronger co-stimulation with TH2 responses contrasts with the ability of higher concentrations of antigen mostly to induce TH1 responses, whereas lower doses induce TH2 responses, suggesting that T helper cell differentiation may be influenced differently by the strength of signals through the CD3/TCR complex versus signals delivered through co-stimulators and their associated enzymes.[71]

1.1.3.2 T HELPER CELL PARADIGMS

The role of cytokines in regulating immune responses can be illustrated best in two scenarios, the first involving the induction of a TH1 immune response to viral infection and the second involving an allergic response to inhaled mold antigens. In the first scenario, viral antigen present at the site of an ongoing infection in the respiratory tract is processed by resident macrophages via the exogenous pathway. The processed epitope is presented on the surface of the macrophage or a dendritic cell in the context of MHC II antigen to a $CD4^+$ T cell in a regional lymph node. These cells produce IL-12 that induces natural killer cells, attracted to the site of the infection, to produce interferon-γ that, along with antigen presentation, activates the T cell and drives it towards a TH1 phenotype. Meanwhile, $CD8^+$ T cells encounter viral antigen on the surface of virus-infected cells that has been processed via the endogenous pathway and is now associated with the MHC I antigens on the infected cell surface. Once antigen-activated, these T cells express the high-affinity form of the IL-2 receptor. The $CD4^+$ TH1 cell produces IL-2 and interferon-γ. The interaction of IL-2 with its receptor drives the clonal proliferation of the activated $CD8^+$ T cells. The interferon-γ also stimulates $CD8^+$ cells to differentiate into CTLs that produce additional interferon-γ. These CTLs can lyse the target cells through production of TNF-α or via activation of the *fas* receptor on the target cell via the *fas* ligand expressed on the activated CTL. Both pathways lead to target cell apoptosis via the activation of cytoplasmic caspases in the target cell. Meanwhile, virus-specific B cells have encountered antigen and, in the presence of interferon-γ, differentiate into IgG-secreting plasma cells. This combination of IgG antibodies and CTL cells serve to eliminate the virus. Prostaglandin E_2 and IL-10 production by macrophages exert antiinflammatory effects on the response and that, coupled with the production of soluble cytokine receptors, dampens the immune response as the invader is eliminated.

In the second scenario, the introduction of mold antigens into the respiratory tract leads to the processing of antigen by macrophages and dendritic cells as described previously. However, in the absence of IL-12 and interferon-γ and perhaps the presence of IL-3, IL-4, IL-9, IL-10, or PGE_2, induction of TH2 cells produces additional IL-4 and IL-13. These cytokines cause those B cells recognizing the allergens to switch isotype to IgE antibodies that bind to mast cells. Subsequent degranulation of these mast cells, resulting from antigen binding to the IgE, leads to the production of other mediators, including IL-4 and PGE_2 that exacerbate this response. In the continued presence of the allergen, a secondary inflammatory response develops characteristic of recurrent airway obstruction.

1.1.3.3 ROLE OF CYTOKINES IN THE HORSE

The field of equine immunology continues to expand with the development of better reagents. Recent advances in gene cloning technology have led to the cloning and expression of a number of equine cytokines. A number of equine cytokines have been cloned and sequenced, and specific protocols are now available to measure their expression (Table 1.1-7). Using these procedures, identifying the role of TH1 and TH2 cells in protective and pathologic responses in the horse has been possible (Table 1.1-8).[69,72,73] The results from these and other studies confirming the role of inflammatory cytokines in equine sepsis and joint and airway diseases emphasize the similarities between equine and human immune systems. As such, the potential for manipulating these responses using recombinant cytokines or anticytokine reagents is as applicable to equine medicine as to human medicine.

1.1.3.4 LYMPHOCYTE TRAFFICKING PATHWAYS

Leukocyte trafficking has been reviewed already, with a particular emphasis on the innate immune response. Lymphocytes involved in adaptive immune responses differ in their migration in that they recirculate instead of making one-way trips. Memory and naïve T lymphocytes, with their different capacities for response to antigen, differ also in their migration pathways through the body. Two general pathways of lymphocyte recirculation have been demonstrated. Naïve T lymphocytes take the most common route, which involves entry into the lymph node by extravasation from the high endothelial venule (HEV) and return to the peripheral circulation via the efferent lymphatic. The endothelial cells of HEVs have a distinctive appearance and specialized receptors and can support a large lymphocyte migration. Such characteristics allow rapid repeated 22
circulation of naïve lymphocytes through lymph nodes to where the greatest chance of exposure to their 23
specific antigens occurs. Memory lymphocytes leave the bloodstream in peripheral vascular beds, particularly in inflamed tissues, and return to lymph nodes via afferent lymphatics. This circulation leads to the exposure of primed memory lymphocytes to the most likely early sites of antigenic encounter and allows for an early response to recall antigens. Thus memory lymphocytes are most common in inflammatory lesions and in the epithelial surfaces of the lung and gut wall. Differing expression of the adhesion and homing molecules may play an important role in mediating these different migration pathways.

TABLE 1.1-7 Cloned Equine Cytokines

CYTOKINE*	GENEBANK ACCESSION NUMBERS†
IL-1	D42146, E13117, E13117, U92480
IL-1	D42147, D42165, E13118, U92481
IL-2	L06009, X69393
IL-4	L06010, AF305617, AF035404
IL-5	U91947
IL-6	U64794, AF005227, AF041975
IL-8	AF062377

MCP-1	AJ251189
MCP-2	AF506972
TGF-β	AF175709

* *IL,* interleukin; *TNF,* tumor necrosis factor; *GM-CSF,* granulocyte-macrophage colony-stimulating factor; *G-CSF,* granulocyte colony-stimulating factor; *MCP*, macrophage chemotactic protein; *TGF,* transforming growth factor.

† Multiple accession numbers indicate multiple reports of sequences for the same genes with the exception of the interferons, for which multiple gene families exist.

TABLE 1.1-8 Helper Cell Paradigm in the Horse

CELL TYPE	PROTECTION	IMMUNOPATHOLOGY
TH1	Equine influenza virus	Equine recurrent uveitis
TH2	*Strongylus vulgaris*	Recurrent airway obstruction (chronic obstructive pulmonary disease and summer pasture-associated obstructive pulmonary disease

For lymphocytes to follow the maturation and migration pathway previously described, the first step is for the naïve lymphocyte to get into a lymph node so that it can meet its antigen on a professional antigen-presenting cell. To achieve this, the T-lymphocyte must exit in the HEV. The naïve lymphocyte expresses L-selectin, which can bind to the vascular addressins GlyCAM-1, CD34, and MAdCAM-1, which are expressed on HEVs and promote rolling similar to that mediated by P- and E-selectin when they bind to phagocytes. These molecules are expressed on a variety of tissues, but in HEVs they have specific patterns of glycosylation that permit binding to L-selectin. These differences represent the key to the specificity of the migration of lymphocytes to HEVs. This weak interaction initiates the process of extravasation, which is promoted by locally bound chemokines (e.g., IL-8) that increase the affinity of the lymphocyte integrins for their ligands.

Approximately 25% of lymphocytes passing through an HEV leave, and this could mean 1.4×10^{4} cells in a single lymph node every second. In the human body, 5×10^{6} lymphocytes may extravasate through HEVs every second. The "sticking" process (rolling, activation, and arrest) takes a few seconds, with transendothelial migration and passage through the HEV basement membrane occurring in about 10 minutes. After leaving the blood, most T cells travel through the lymph node uneventfully and leave via efferent lymphatics; however, in rare events a naïve T cell recognizes its specific peptide-MHC complex and becomes activated, eventually leading to formation of effector and memory T-cells. That process takes 4 to 5 days, and once activated, the migration pathway of memory T-cells differs considerably from naïve cells. All activated T-cells lose the L-selectin molecules that mediated homing to lymph nodes and increase the expression of other adhesion molecules. The homing of individual lymphocytes to specific sites is regulated by expression of specific adhesion molecules. Memory cells are attracted specifically to areas of inflammation because of the increased concentrations of adhesion receptor ligands expressed on vascular endothelium in these regions. The inflammation typically results from TNF-α production by regional macrophages encountering infections. Memory cells also migrate randomly throughout the body. When memory cells encounter their antigen, they can produce cytokines such as TNF-α, which in turn causes local endothelial cells to increase expression of E-selectin, vascular cell adhesion molecule 1, and intracellular adhesion molecule 1. Such expression 23
subsequently causes recruiting of more effector and memory cells to the region. 24

1.1.3.5 ONTOGENY OF THE EQUINE IMMUNE SYSTEM

Few studies of the prenatal development of the equine immune system have been done. As in other species, the thymus is the first lymphoid organ to develop, and mitogen responsive cells can be identified in the organ from day 80 of the 340-day gestational period of the horse.[74] Subsequently these cells appear in peripheral blood at 120 days, in lymph nodes at 160 days, and in the spleen at 200 days. Cells responsive in mixed lymphocyte reactions are detectable in the thymus at 100 days and in the spleen at 200 days. Immunoglobulin production is detectable before 200 days, and newborn foals typically have IgM concentrations in their serum of

approximately 165 μg/ml. Overall, functional T lymphocytes apparently are present by day 100 and B lymphocytes by day 200 of gestation. Immunologic competence of the equine fetus has been assessed in terms of specific antibody responses. In utero immunization of foals in late gestation with keyhole-limpet hemocyanin in an alum adjuvant results in detectable specific antibody production and T cell responsiveness at the time of birth.[75] In addition, the equine fetus can respond to coliphage T2 at 200 days and to Venezuelan equine encephalitis virus at 230 days.[76,77]

Detailed studies of the appearance of lymphocyte subpopulations defined by monoclonal antibodies have not been performed in the equine fetus. However, some information regarding the maturation of thymocytes in young horses is available. During thymic maturation of T cells, stem cells migrate into the thymus and mature into T cells under the influence of the epithelial microenvironment.[78,79] In this process, different patterns of cell surface differentiation antigen expression distinguish successive stages of thymocyte maturation. In human beings the earliest thymic precursor cells express low levels of CD4.[80] This CD4 expression is lost as early thymocytes become double-negative $CD4^{-}CD8^{-}$ cells and then demonstrate their T cell commitment by TCR-β gene rearrangement, which is an essential trigger for subsequent events and leads to low levels of expression of a cell surface TCR-β–CD3 complex.[81] Intermediate thymocytes are $CD4^{lo}CD8^{lo}$, but after TCRα gene rearrangement and expression of cell surface TCR-αβ they rapidly become $CD4^{hi}CD8^{hi}TCR\text{-}CD3^{hi}$.[80] Subsequently thymocytes selected on the basis of productive TCR gene rearrangement and lack of self-reactivity become mature T cells expressing CD4 or CD8 (single positive) in combination with high levels of TCR-CD3. Using two-color fluorescence-activated cell sorter analysis, similar patterns of EqCD3, EqCD4, and EqCD8 antigen expression in the equine thymus can be demonstrated.[82,83]

1.1.3.6 IMMUNOCOMPETENCE IN FOALS

Infectious disease in neonatal foals is associated with high morbidity and mortality. Although failure of passive transfer is a major cause of this problem, as discussed in Chapter 1.3, immaturity of the immune system also has been considered a potential contributing factor. As a result, a number of studies of neonatal immunocompetence have been completed.

1.1.3.7 INNATE IMMUNE RESPONSES IN FOALs

A number of studies have reported neutrophils to be fully functional from birth[84–86]; however, neutrophil function is impaired significantly before absorption of colostral antibodies, which are required for opsonization.[86,87] A recent study of foal neutrophil development over the first 8 months of life demonstrated killing (measured by chemiluminescence) to be reduced in the first 2 weeks of life, as was phagocytic ability when assays were performed using autologous serum.[88] When serum from adult horses was used, neutrophil phagocytic ability in foals was normal. This latter difference may have been caused by absence of adequate immunoglobulin or complement in foal serum. A similar study of foals less than 7 days of age confirms that phagocytosis and oxidative burst activity of neutrophils is reduced in foals of this age, although the use of adult serum did not improve phagocytosis.[89] Sim ilarly, alveolar macrophages recovered from bronchoalveolar lavage fluid may be low in number up to 2 weeks of age and may have impaired chemotactic function.[90]

The importance of complement in foals is illustrated by the finding that the opsonic capacity of foal serum for bacteria is halved by heat inactivation.[91] Interestingly, complement activity in the first week of life is increased

considerably in colostrum-deprived foals, possibly as an alternative defense mechanism.[92] In foals fed bovine colostrum, serum complement concentrations reach adult concentrations by 1 to 3 weeks of age.[93]

1.1.3.8 ADAPTIVE CELL-MEDIATED IMMUNITY IN FOALS

Recent studies have measured lymphocyte numbers and subpopulations in foals.[94–96] Foals are born with B and T lymphocytes and with $CD4^+$ and $CD8^+$ T lymphocyte subsets. Lymphocyte counts increase in the first 4 months of life, and the proportion of B lymphocytes increases. A comprehensive study of lymphoproliferative responses in foals from the day of birth through 4 months of age found no difference between foals and adults.[96] Another study reported foal lymphoproliferation as low on the day of birth, possibly because of high serum cortisol levels.[97] Currently, markers for the development of memory lymphocytes are unavailable in horses, although increased expression of MHC II antigen on T lymphocytes throughout the first year of life may 24
identify a developing population of memory cells.[98] Although evidence exists for the capacity of foals to mount 25
immune responses in utero,[75–77] few studies of antigen-specific immune responses in the first days of life have been done except in the context of the immunosuppressive effect of passive transfer of immunity.[99] When foals are immunized with antigens against which they have no maternally derived specific antibodies, clearly they can mount immune responses from at least 3 months of age and possibly sooner.[100]

1.1.3.9 ANTIBODY-MEDIATED IMMUNITY IN FOALS

1.1.3.9.1 Passively Transferred Maternal Antibody

During the first 1 to 2 months of life, foals depend on passively transferred immunity for protection from infectious disease. The diffuse epitheliochorial nature of the equine placenta does not allow for in utero immunoglobulin transfer to foals. Although minor concentrations of some immunoglobulins can be detected at birth, the foal is born essentially agammaglobulinemic and acquires passive immunity by the ingestion and absorption of colostrum from the dam.[101,102] Colostrum is a specialized form of milk containing immunoglobulins, which are produced during the last 2 weeks of gestation under hormonal influences.[103] Colostrum contains primarily IgGa, IgGb (IgGa plus IgGb is the equivalent of IgG), and IgG(T), with smaller quantities of IgA and IgM, all of which have been concentrated into mammary secretions from the blood of the mare.[104,105] Colostrum is produced only one time each pregnancy and is replaced by milk that contains negligible immunoglobulins within 24 hours of the initiation of lactation.[104,106] This rapid decline in immunoglobulin concentrations in mammary secretions is consistent with equine colostrum production ending at or even before parturition.[105] The absorptive capacity of the gastrointestinal tract of the foal for immunoglobulins is greatest during the first 6 hours after birth and then steadily declines until immunoglob ulins can no longer be absorbed when the foal is 24 hours old. This closure of the gut to absorption of large intact molecules is caused by replacement of specialized enterocytes by more mature cells.[107]

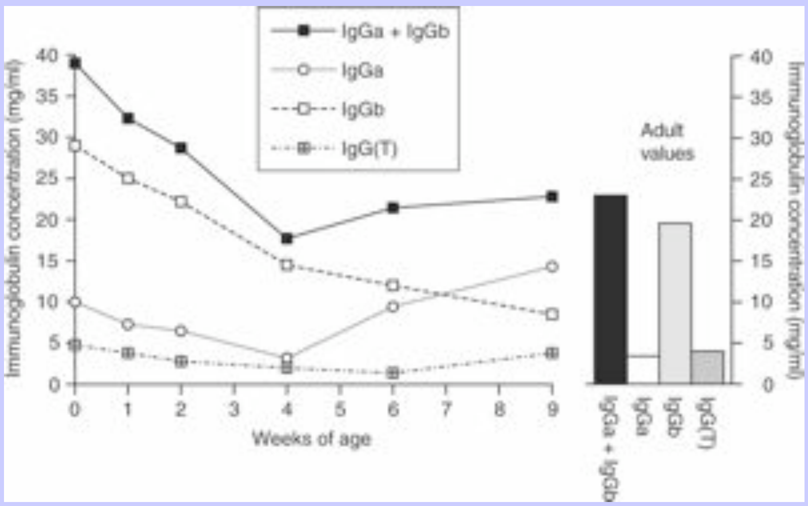
1.1.3.9.2 De Novo Antibody Production in Foals

Few studies of de novo antibody production have been conducted in foals without the effect of passively transferred maternal antibody. In a study of 10 pony foals fed only bovine colostrum, endogenous equine antibody production measured by radial immunodiffusion resulted in serum concentrations of IgG of 200

mg/dl by 2 weeks of age, 400 mg/dl by 1 month, and 1000 mg/dl by 3 months of age.[108] In a smaller study of two colostrum-deprived pony foals, comparing them with 18 colostrum-fed foals and measuring serum γ-globulin levels by immunoelectrophoresis, similar results were obtained, although the colostrum-deprived foals apparently achieved higher serum γ-globulin levels between 6 weeks and 3 months of age than colostrum-fed foals.[101] In a third study, antibody concentrations in six colostrum-deprived foals were substantively higher than in five control foals between 3 and 5 months of age.[92] These three studies provide evidence for substantial endogenous production of IgG in the first month of life in foals deprived of equine colostrum and suggest that the onset of production is earlier and the rate is higher in foals deprived of colostrum. This observation is consistent with nonspecific immunosuppression in colostrum-fed foals or to stimulation of immunoglobulin production in colostrum-deprived foals. In another study of foals from mixed-breed horses fed only bovine colostrum, endogenous IgG production started later and was detected first at 1 month of age in the majority of foals, reaching similar levels in foals fed equine colostrum by 2 months of age.[109]

In colostrum-fed foals, serum IgG concentrations fall to their lowest level at 1 to 2 months of age because of catabolism of maternally transferred immunoglobulin, subsequently rising toward adult levels because of endogenous immunoglobulin production.[88,95,96,102] A study by Sheoran, Timoney, Holmes et al.[105] extended these observations and extensively documented changes in serum IgG subclass concentrations in five Quarter Horse foals in the first 9 weeks of life (Figure 1.1-17). This study showed that IgG (the equivalent of IgGa plus IgGb) concentrations were lowest at 1 month of age. However, the subsequent increase in IgG concentration was due to de novo IgGa production, not IgGb. At the end of this study, at 9 weeks of age still no clear evidence of IgGb production was observed, although IgGa and IgG(T) concentrations had reached or exceeded adult levels. In adult horse serum, IgGb comprises greater than 60% of total serum IgG and is by far the dominant subclass in foal serum after passive transfer of immunity. IgGb also plays a critical role in immunity to a variety of pathogens,[110,111] and possibly the naturally late onset of endogenous production may be a factor in the increased susceptibility of foals at this age to infections such as bacterial respiratory disease.[112,113] This possibility was investigated in a study by Grondahl, Sternberg, Jensen-Waern et al.,[91] in which the opsonic capacity of foal serum was measured during the first 42 days of life using the foal pathogens *Escherichia coli* and *Actinobacillus equuli*. No differences were detected over time, and foal serum was as effective as adult horse serum. Although this study did not provide evidence of decreased opsonization in serum of older foals, the studies were extended only to samples from 42-day-old 25
foals, and in this in vitro system immunoglobulin concentrations may not have been rate limiting. Further 26
investigation of the role of naturally low immunoglobulin subclass concentrations in the pathogenesis of respiratory infections of foals is warranted.

Figure 1.1-17 Immunoglobulin G subclass concentrations in foals and adults. Line graph shows mean serum concentrations of serum IgG subclass data from five Quarter Horse foals during the first 9 weeks of life as measured using an enzyme-linked immunosorbent assay system. Bar graph shows mean adult concentrations measured in 27 mixed-breed horses. (Data is from Sheoran, Timoney, Holmes, et al. 105)



A factor that significantly affects de novo immune responses in foals is the suppressive effect of passively transferred antigen-specific maternal antibodies. The rate of decline of these antibodies varies for individuals and different infectious agents. The half-life for maternal IgG in foals is estimated at 20 to 30 days.[106] Recent studies of antigen-specific antibodies demonstrated similar half-lives for antiinfluenza virus and antitetanus antibodies of 27 to 29 days for IgGa, 35 to 39 days for IgGb, and 35 days for IgG(T).[114] For many important pathogens, the concentration of maternal antibodies in foals falls to nonprotective levels by 2 to 3 months of age.[115,116] However, the remaining antibody still may render the foal unresponsive to vaccination for weeks or even months. In the case of equine influenza virus[117,118] and tetanus toxin, maternal antibodies can persist until 6 months of age and prevent immune responses in foals vaccinated before that age.[114] When foals are vaccinated against antigens against which they have no passively transferred antibody, normal antibody responses have been documented from at least 3 months of age.[100]

1.1.3.10 IMPLICATIONS FOR IMMUNOCOMPETENCE IN FOALs

The evidence presented suggests that the immune system of a foal is competent in many regards, with the innate immune system completely functional at least by the second week of life and with the full complement of lymphocytes present from birth. Antibody is provided entirely by passive transfer at first, although endogenously produced immunoglobulin is detectable within a few weeks of birth and predominates from 1 to 2 months of age. Nevertheless, some key features of the foal immune system can limit its ability to defend

against infection. A critical factor is antigen-specific and nonspecific immuno suppression resulting from transferred maternal antibody. As the foal ages, the continuing immunomodulatory effect of maternal antibody may limit foal immunoresponsiveness while no longer providing comprehensive protection itself. Of similar importance is the fact that although the lymphocytic immune system is complete from the time of birth, it is naïve. Neonates can mount normal immune responses but require appropriate presentation of antigen and co-stimulatory signals.[119] Antigen presentation in the absence of co-stimulatory second signals from (for example, T helper cells) can induce immune deviation or a failure to mount the appropriate immune response, and particularly so in neonates.[120–122] The absence of memory responses and a well-developed repertoire of immune responses is a serious handicap that only appropriate antigenic encounters can overcome.

1.2 1.2—Hypersensitivity and Autoimmunity

D. Paul Lunn

David W. Horohov

Hypersensitivity refers to an altered state of immunoreactivity resulting in self-injury. Four different types of hypersensitivity are defined by the type of immunologic process underlying the tissue injury, as originally proposed by Coombs and Gell.[1] Table 1.2-1 presents the general features of this classification system. The most common and important type of hypersensitivity disease is type I hypersensitivity, mediated by immunoglobulin E (IgE). In these diseases, individuals produce IgE antibodies against a normally innocuous antigen, termed an allergen. Exposure to the allergen triggers mast cell degranulation as described later, and a series of responses result that are characteristic of allergy. Allergic diseases are so important that more is known about the function of IgE in this hypersensitivity disease than about its normal role in host defense. Throughout this chapter, the term *allergy* refers only to type I hypersensitivity diseases mediated by IgE.[2] Other authors may use the term *allergy* to refer to the entire spectrum of hypersensitivity diseases.[3] Other forms of hypersensitivity disease depend on IgG antibodies (type II and III hypersensitivities) or T cells (type IV hypersensitivity). Each of these disease processes can play a role in the immunopathogenesis of autoimmune disease, in which the body mounts an adaptive immune response to self-tissue antigens.

Clinical hypersensitivity diseases such as recurrent airway obstruction (RAO) or purpura hemorrhagica may result
from more than one type of hypersensitivity reaction, limiting the use of this classification for clinical diagnosis. 29
Alternative strategies for classifying these diseases may have greater clinical use. For example, antibody-mediated 30
hypersensitivity diseases (types I, II, and III) are immediate in onset if preformed antibody exists in circulation or tissues, with some variation in time course depending on the antibody isotype involved. Cell-mediated hypersensitivity (type IV) reactions are delayed, even in sensitized individuals, for 1 to 3 days, whereas effector cells are recruited to the site of antigen exposure.[3] The goals of this section are as follows:

- Review the classical hypersensitivity types to explain the immunopathogenesis of hypersensitivity diseases.
- Describe immediate and delayed hypersensitivities of horses and their immunologic basis.
- Identify autoimmune conditions of horses with a known immunologic basis.

Detailed descriptions of clinical aspects of hypersensitivity and autoimmune diseases, their diagnosis and management, are presented elsewhere in this book. Detailed explanations of many immunologic mechanisms involved in these disease processes are provided in Chapter 1.1.

TABLE 1.2-1 The Four Types of Hypersensitivity[*]

	HYPERSENSITIVITY TYPE					
				IV		
Traits	I	II	III			
Immune mediator[†]	IgE	IgG	IgG	TH1	TH2	CTL
Antigen	Soluble antigen	Cell or matrix associated antigen	Soluble antigen in excess (immune complex formation)	Soluble antigen	Soluble antigen	Cell-associated antigen
Effector mechanism	Mast cell degranuation	Fc-receptor–positive cells (phagocytes of reticuloendothelial system)	Fc-receptor–positve cells; complement	Macrophage activation	Eosinophil activation	Cytotoxicity
Examples of hypersensitivity reaction	Systemic anaphylaxis; *Culicoides* hypersensitivity	Penicillin-associated hemolytic anemia	Serum sickness in human being	Equine recurrent uveitis	Chronic *Culicoides* hypersensitivity	Contact dermatitis

* The four types of hypersensitivity can be differentiated by the immune mediator involved, the form of antigen recognized, and the effector mechanism elicited in producing the pathologic response. Equine examples of each condition are given when available.

† *Ig,* Immunoglobulin; *TH,* T helper cell (type 1 or 2); *CTL,* cytotoxic T lymphocyte.

1.2.1 Classical Types of Hypersensitivity Reaction

1.2.1.1 TYPE I HYPERSENSITIVITY

As described previously, type I hypersensitivity, or allergy, is mediated by IgE antibody specific for allergens, which are extrinsic antigens normally not recognized by the healthy immune system.[2] IgE is found predominantly in tissues, where it is bound to mast cells through the high-affinity IgE receptor FcεRI.[4] When antigen binds to IgE on the surface of mast cells, cross-linking two or more IgE molecules and their FcεRI receptors, it triggers the release of chemical mediators from mast cells, which cause type I hypersensitivity reactions. Basophils and eosinophils (when activated) also possess FcεRI receptors and therefore can participate in the same process. In addition to FcεRI receptors, an unrelated low-affinity IgE receptor called CD23 is present on many lymphocytes, monocytes, eosinophils, platelets, and follicular dendritic cells. The role of CD23 appears to be to enhance IgE responses to specific antigens when those antigens are complexed with IgE. Thus CD23 on antigen presenting cells can capture IgE-bound antigens. In the horse CD23 has been identified, and its expression is upregulated by equine interleukin-4 (IL-4).[5]

The selective stimulation of IgE responses depends on characteristics of the antigen (allergen), the individual affected (genetic factors such as major histocompatibility complex [MHC] antigens), and the mechanism of antigen presentation. The antigen must be capable of eliciting a type 2 T helper cell (TH2) immune response to

stimulate IgE production. Small, soluble proteins (frequently enzymes) containing peptides suitable for MHC II antigen presentation and presented to mucosal surfaces at low doses are particularly efficient at generating IgE responses. Low doses of antigen specifically favor TH2 over TH1 responses, and exploiting this relationship is the basis of some therapeutic hyposensitization strategies (see Chapter 1.4). When CD4 T-helper cells are exposed to IL-4, as opposed to IL-12, during antigen presentation by dendritic cells, they are driven toward becoming TH2 cells. This process is critical to promoting IgE responses and may be favored at enteric and respiratory mucosal surfaces or on skin, where parasite invasion typically occurs. This makes teleologic sense, 30
because IgE responses are important for antiparasitic immunity.[6] The dendritic cells at such locations 31
frequently are programmed to stimulate TH2 responses.[2] Cross-linking of FcεRI receptors on granulocytes also results in CD40L expression and IL-4 secretion, which further promotes IgE production by B lymphocytes and sustains allergic reactions.

Some individuals maintain IgE responses to a variety of allergens, and this condition is called atopy. Affected individuals have high levels of IgE in the blood and increased eosinophil populations. In human beings this condition depends partly on genetic factors, including genetic variations in the IL-4 promoter sequence or association with particular MHC II genes. Nevertheless, environmental factors are also important, for atopy is increasingly common in human beings in economically developed parts of the world. Four possible explanations for this are decreased exposure to infectious disease during childhood, environmental pollution, allergen levels, and dietary change. The first explanation currently is favored, and its basis is the proposal that many infectious diseases bias the immune system toward TH1 responses,[2] and that their decreased prevalence results in an increased tendency to mount TH2 responses, which may be the natural bias of the neonatal immune system.[7]

1.2.1.1.1 Effector Mechanisms in Type I Hypersensitivity Allergic Reactions

When triggered by antigen cross-linking of IgE bound to FcεRI cell-surface receptors, activated mast cells release chemical mediators stored in preformed granules and synthesize leukotrienes and cytokines. In type I hypersensitivity reactions the outcome of this reaction can vary from anaphylactic shock to minor localized inflammation. Mast cell degranulation causes an immediate allergic reaction within seconds, but also a sustained late-phase response develops over up to 8 to 12 hours because of recruitment of TH2 lymphocytes, eosinophils, and basophils.

Mast cells are highly specialized cells of the myeloid lineage that are common in mucosal and epithelial tissues near small blood vessels. The range of inflammatory mediators released by degranulating mast cells is extensive and includes enzymes that can remodel connective tissues; toxic mediators such as histamine and heparin; cytokines including IL-4, IL-5, IL-13, and tumor necrosis factor α; chamomiles; and lipid mediators including leukotrienes and platelet-activating factor.[2] Histamine causes an increase in local blood flow and permeability. Enzymes activate matrix metalloproteinases that cause tissue destruction. Tumor necrosis factor α increases expression of adhesion molecules and attracts inflammatory leukocytes. These reactions are all appropriate when the mast cell is reacting to an invading pathogen, but in allergy this response is the basis of the immediate inflammatory response and also the initiating step in the late-phase response.

The role of eosinophils in inflammation is tightly controlled at several levels. Synthesis in the bone depends on IL-5 produced by TH2 cells in the face of infection or other immune stimulation. Transit of eosinophils to tissues depends on two chemokines, eotaxin 1 and eotaxin 2. Activation of eosinophils by cytokines and chemokines induces the eosinophils to express FcεRI and complement receptors and primes the eosinophil

to degranulate if it encounters antigen that can cross-link IgE on its surface. Mast cell degranulation and TH2 activation recruit and activate large numbers of eosinophils at the site of antigen encounter. Basophils are similarly recruited, and together their presence is characteristic of chronic allergic inflammation. Eosinophils can trigger mast cells and basophil degranulation by release of major basic protein. This late-phase response is an important cause of long-term illnesses such as chronic asthma in human beings.

1.2.1.1.2 Clinical Manifestations of Type I Hypersensitivity Reactions Depend on Their Site

The clinical outcome of type I hypersensitivity reactions depends on the amount of IgE present, dose of allergen, and the site of allergen introduction. Direct introduction of allergen into the bloodstream or rapid enteric absorption can lead to widespread activation of connective tissue mast cells associated with blood vessels. This potentially disastrous event is called systemic anaphylaxis and can cause catastrophic loss of blood pressure and airway obstruction because of bronchoconstriction and laryngeal swelling. Anaphylactic shock, for example, can follow administration of drugs against which an individual has an established IgE response. Treatment with epinephrine may control these potentially fatal events.

Penicillin is one example of a drug that can cause type I hypersensitivity reactions in human beings, although the ability of penicillin to induce this type of hypersensitivity reaction in the horse is less certain. Penicillin can act as a hapten (see Chapter 1.1). Penicillin alone can elicit antibody formation by B cells but cannot elicit T helper cell responses because it is not a protein. However, the β-lactam ring of penicillin can react with amino groups on host proteins to form covalent conjugates, and the modified self-peptides can generate TH2 responses in some individuals. The TH2 cells in turn can release cytokines that activate penicillin-binding B cells to produce IgE. In this scenario, penicillin is a B cell antigen and becomes a T cell antigen by modifying self-peptides. Intravenous penicillin results in protein modification and recognition and cross-linking of mast cell IgE leading to anaphylaxis.[2]

Allergen inhalation, in contrast, induces local inflammation of the respiratory tract, for example, in the upper 31
airways as in allergic rhinitis or in the lower airways as in human asthma. Similarly, allergen introduction 32
into the skin causes local histamine release and a wheal-and-flare reaction initially, followed by a late-phase response several hours later. When allergens are ingested and reach the skin from the bloodstream, a disseminated form of the wheal-and-flare reaction occurs that is called urticaria or hives. Prolonged inflammation of the skin results in eczema or atopic dermatitis in some individuals. Ingestion of allergens causes activation of gastrointestinal mast cells resulting in fluid loss across the bowel and smooth muscle contraction. The clinical presentation is diarrhea and vomiting. Sometimes ingestion of allergens can lead to systemic anaphylaxis if allergens are absorbed rapidly or to urticaria, as is sometimes seen after administration of oral penicillin.

1.2.1.2 TYPE II HYPERSENSITIVITY

This form of hypersensitivity disease occurs when the causal antigen is associated with cells or tissue components of the body and an IgG antibody response to this antigen occurs. Phagocytes, or other cells expressing Fcγ receptors, mediate destruction of the affected tissue or removal from the circulation by the reticuloendothelial system in the case of antibody-positive erythrocytes or platelets. Antibody-mediated hemolytic anemia or thrombocytopenia are examples of drug-associated type II hypersensitivities, and in the case of the horse, penicillin is an established cause of hemolytic anemia.[8] Diagnosis can be accomplished using a Coombs' test (Figure 1.2-1). Penicillin binds to the erythrocyte surface and is targeted by antipenicillin

antibodies of the IgG isotype. Interestingly, large numbers of horses have antipenicillin antibodies of the IgM isotype, but this does not lead to disease.

Figure 1.2-1 Direct Coombs' test. *Ab,* Antibody; *RBCs,* red blood cells.

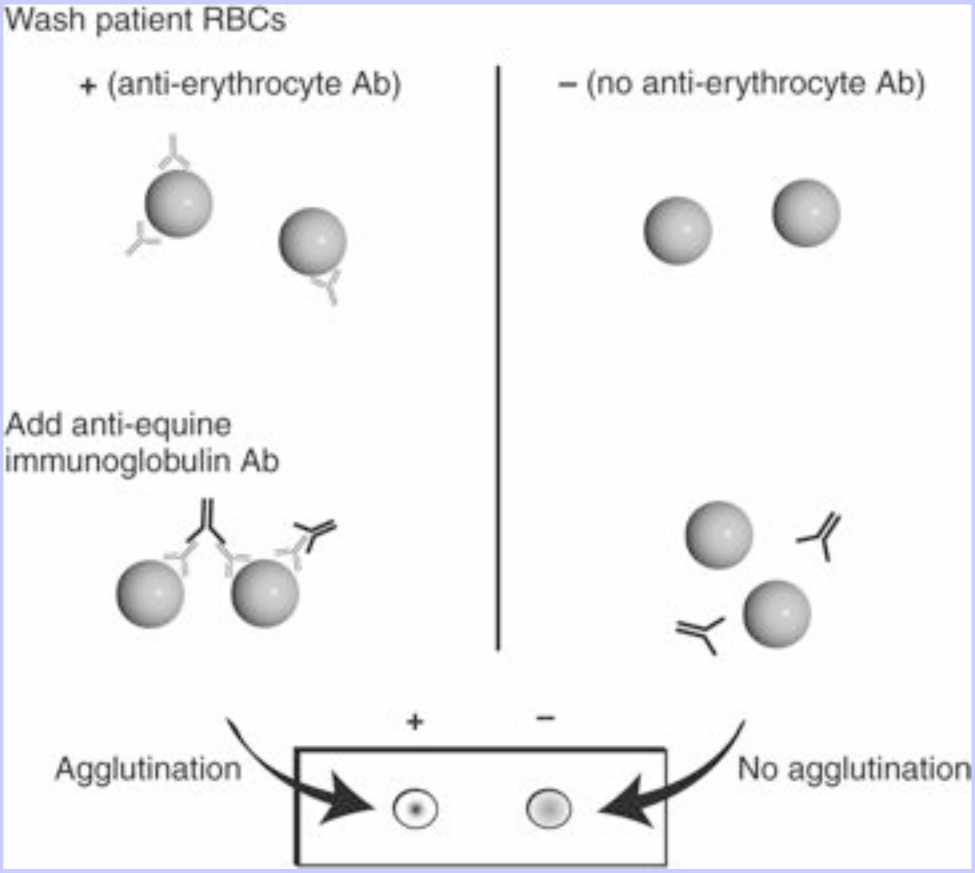

Figure 1.2-2 Antibody-antigen precipitation. Antibody can precipitate soluble antigen in the form of immune complexes. This is most efficient when concentrations of antibody and antigen reach equivalence and large immune complexes are formed. However, when antigen is in excess, some immune complexes are too small to precipitate and can produce pathological changes such as are seen in type III hypersensitivities.

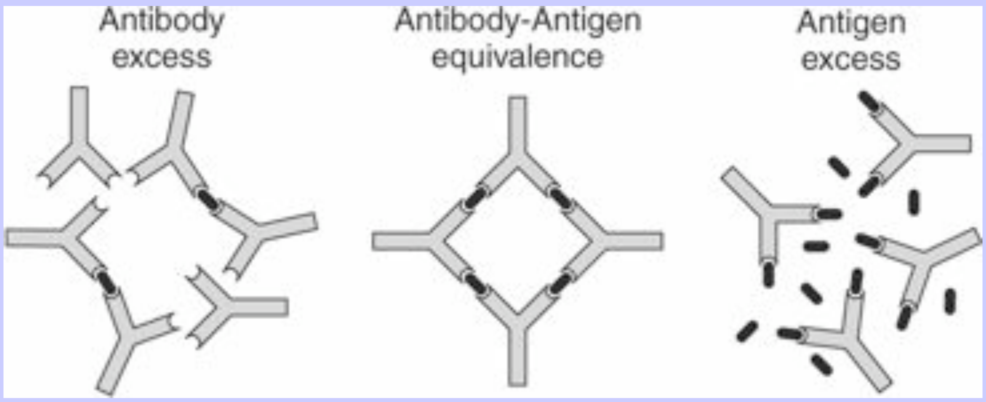

1.2.1.3 TYPE III HYPERSENSITIVITY

In type III hypersensitivity, the antigen is soluble and present in the circulation. Disease results from formation of antibody-antigen aggregates or immune complexes under specific conditions.[2] Although immune complexes are generated in all antibody responses, they are generally harmless. Large complexes fix complement and are removed from circulation by the reticuloendothelial system. However, small complexes can form at antigen excess (Figure 1.2-2), and these can deposit in blood vessel walls and tissues where they ligate Fc receptors on leukocytes, causing an inflammatory response, increased vascular permeability, and tissue injury. Complement activation also contributes to this process. Local injection of antigen sometimes can lead to a necrotizing skin lesion caused by type III hypersensitivity, termed an Arthus reaction.

The classical example of a type III hypersensitivity reaction is serum sickness, which is seen after administration of horse antiserum in human beings, for example, in treating snake bites. After an IgG response to the horse serum is generated (7 to 10 days), signs of fever, urticaria, arthritis, and sometimes glomerulonephritis result. The foreign antigen is cleared as part of this process, which makes this condition ultimately self-limiting. Alternative scenarios for induction of type III hypersensitivity reactions include persistent infectious diseases in which pathogens are not cleared completely from tissues or autoimmune diseases. Inhaled antigens that induce IgG responses can lead to immune complex formation in the alveolar wall, as occurs in farmer's lung, compromising lung function.[2] Any such circumstance in which immune complexes are deposited in tissues can lead to this type of pathologic response. 32

1.2.1.4 TYPE IV HYPERSENSITIVITY

Cell-mediated type IV hypersensitivities cause delayed hypersensitivity reactions. A variety of cutaneous hypersensitivity reactions are seen, such as the contact hypersensitivity seen after absorption of haptens such as pentadecacatechol in poison ivy or the local TH1 response seen in the diagnostic tuberculin reaction. When type IV hypersensitivity results in a TH2 response, the principle outcome is eosinophil activation and recruitment such as in chronic asthma.

1.2.2 Immediate Hypersensitivity Diseases

A major limitation in the ability to study hypersensitivity disease in the horse has been the limited availability of reagents capable of detecting equine IgE. Although equine IgE has long been known to exist,[9,10] and the genetic sequence has been known since 1995,[11–13] the only reagents for studying it have been conventional polyclonal antisera produced by vaccination with physicochemically purified IgE[14,15] or made in chickens after vaccination with recombinant fragments of the IgE heavy chain.[16] Although many valuable studies have been performed using these reagents,[17–20] the development of well-characterized monoclonal antibodies recognizing equine IgE remains a critically important goal for equine immunologists. At the time of writing, this goal seems likely to be realized soon by a number of groups,[21] and future clinical studies and investigations should benefit from this advance.

The following section describes a series of equine diseases with characteristics of immediate hypersensitivity disease. The list of equine hypersensitivity diseases is not exhaustive, and additional examples are found throughout this book.

1.2.2.1 SYSTEMIC ANAPHYLAXIS

The incidence of true systemic anaphylaxis in horses is unknown, although the condition has been reported in association with administration of a wide range of compounds including serum, vaccines, vitamin E–selenium preparations, thiamine, iron dextrans, and antibiotics including penicillin.[22,23] Target organs in experimental equine anaphylaxis are the lung and the intestine.[22] Sudden dyspnea; hypotension, as evidenced by poor peripheral pulse character; rapid onset of urticaria; and collapse are cardinal signs of the onset of systemic anaphylaxis.

The therapeutic goals in treating systemic anaphylaxis are to prevent or reverse the complications caused by mediator release, maintain respiratory integrity, and maintain cardiovascular stability. Not all anaphylactic reactions require therapy. However, rapid recognition of those that do is critical to patient survival. Intravenous access via an indwelling catheter and airway patency should be assured immediately because cardiovascular collapse and upper airway obstruction caused by angioedema can occur rapidly. The conscious horse does not tolerate tracheal intubation, so emergency tracheotomy may be required. Oxygen should be administered if available because bronchoconstriction and cardiovascular collapse result in hypoxemia. The fluid requirement of horses in anaphylactic shock is not known, but large volumes of balanced polyionic fluid should be administered rapidly.

The principal therapeutic agent is epinephrine, which is a potent sympathetic stimulant. Epinephrine administration may cause excitement in the horse. Epinephrine should be administered intramuscularly (10 to

20 μg/kg, equivalent to 5 to 10 ml of 1:1000 dilution of epinephrine for a 450-kg horse) if dyspnea or hypotension are mild. Epinephrine should not be administered subcutaneously because its potent vasoconstriction can lead to poor absorption and tissue necrosis. If dyspnea or hypotension is severe, epinephrine should be administered intravenously or endotracheally if no venous access is available (3 to 5 μg/kg or 1.5 to 2.25 ml of 1:1000 dilution of epinephrine for a 450-kg horse). Epinephrine doses can be repeated every 15 to 20 minutes until hypotension improves. The side effects of epinephrine therapy are tachyarrhythmias and myocardial ischemia, which in themselves can be life threatening. Alternatively, an epinephrine or norepinephrine drip can be used in cases of refractory hypotension. Other therapeutic agents such as antihistamines, β-agonists, or other pressors may be indicated, although their value is less certain. Though the effects may be delayed, glucocorticoid therapy is indicated to help reverse persistent bronchospasm and angioedema and to break the cycle of mediator-induced inflammation triggered during hypersensitivity reactions. Ideally, a rapid-acting glucocorticoid such as prednisolone sodium succinate (0.25 to 10.0 mg/kg intravenously) should be used. Glucocorticoid therapy during the acute phase aids in preventing the late-phase reaction.

1.2.2.2 INSECT HYPERSENSITIVITY

Horses commonly suffer from hypersensitivity to salivary antigens of *Culicoides* and *Simulium* species, leading to an intensely pruritic skin disease with characteristics of immediate and delayed-type hypersensitivity.[24] The clinical sign of urticaria, combined with increased numbers of IgE positive cells in the skin and high levels of *Culicoides*-specific IgE in serum, are evidence of immediate (type I) hypersensitivity in the immunopathogenesis of this disease.[17,18] In some breeds a genetic predisposition based on an MHC-linkage has been demonstrated.[25,26]

1.2.2.3 RECURRENT AIRWAY OBSTRUCTION

RAO is a severe inflammatory disease of middle-aged and older horses induced by exposure of susceptible 33
horses to inhaled organic dust, generally from hay, although a summer pasture-associated form also is observed 34
in the southern United States.[27] Hay dust contains a mixture of mold spores, forage mites, particulates, and endotoxins, which can induce and exacerbate airway inflammation. Removal of the hay dust by returning the horse to pasture leads to decreased inflammation within a few days. In RAO-susceptible horses, exposure to hay dust leads to invasion of the lungs and airways by neutrophils within 4 to 6 hours and concurrent airway obstruction caused by bronchospasm, inflammation, and increased mucus viscosity, which principally affect the bronchioles. RAO-affected horses develop nonspecific airway hyperrespon siveness, bronchospasm, in response to a variety of stimuli including inflammatory mediators and neurotransmitters. Horses affected by RAO demonstrate increased histologic lesions and worsening airway function with increasing age. In addition, significant histopathologic changes are present before abnormal airway function can be detected.

The immunologic basis of RAO remains poorly elucidated. Two pieces of evidence suggest a type I hypersensitivity basis to this disease. First, IgE levels are increased in bronchoalveolar fluid of RAO-affected horses,[14] and second, allergen-specific IgE is increased in affected horses.[20,28] However, the immediate onset of airway obstruction typical of a type 1 reaction to exposure to allergens is never observed because clinical signs are only apparent several hours after antigenic exposure.[27] A number of immunologic processes, including IgE-mediated pathologic processes, may be involved in this disease. A study of immunoregulatory cytokines in RAO using in situ hybridization demonstrated evidence for a TH2 bias in RAO, with increased levels of IL-4 and IL-5 and decreased interferon-γ messenger RNA in bronchoalveolar cells.

Evidence indicates that the neutrophilic inflammation characteristic of RAO in horses is induced by IL-8 production, and IL-8 levels in bronchoalveolar fluid are increased in RAO-affected horses.[29,30] When RAO-susceptible horses are antigen challenged, peripheral blood and airway neutrophils are primed, as demonstrated by increased superoxide production and respiratory burst activity. In airways, neutrophil degranulation products are increased, including neutrophil elastase and matrix metalloproteinase 9 (MMP-9). Much of the neutrophil elastase is inactive, and much of the MMP-9 is active. However, in contrast to human chronic obstructive airway disease, airway remodelling in RAO-affected horses is minimal. During the resolution of RAO, apoptosis of airway neutrophils is increased, and consequently neutrophil function and the resulting tissue damage are reduced. In contrast, during exacerbations of RAO, neutrophil apoptosis is reduced, possibly through cytokine-mediated upregulation of NF-κB.[31]

1.2.2.4 IMMUNOGLOBULIN G–MEDIATED DISEASES

These conditions, which broadly correspond to type II and III hypersensitivities, also have been termed *immune-complex diseases* in the horse.[3] The examples described subsequently are distinguished from other immediate hypersensitivities of the horse described previously in that no evidence exists for the involvement of IgE in their pathogenesis.

1.2.2.4.1 Neonatal Isoerythrolysis and Alloimmune Thrombocytopenia

Neonatal isoerythrolyis is a common condition of foals and is reviewed extensively elsewhere in this text. The condition results from the passive transfer of maternal antibodies in colostrum that recognize allogenic foal erythrocyte antigens principally of the Aa and Qa haplotype inherited from the sire. A similar condition occurs in mules because of inheritance of a donkey-specific erythrocyte antigen.[32,33] A severe, potentially life-threatening anemia results as the antibody-positive erythrocytes are removed by the reticuloendothelial system or, less commonly, are lysed by complement. A similar condition less commonly affects platelets, causing severe neonatal thrombocytopenia in horses[34] and mules.[35] These conditions are typical of type II hypersensitivities and are mediated by circulating IgG recognizing cell surface antigens on erythrocytes. Diagnosis can be performed using a variation of the Coombs' test (Figure 1.2-3).

1.2.2.4.2 Purpura Hemorrhagica

Purpura hemorrhagica is an acute disease of the horse characterized by edema of the head and limbs; leukocytoclastic vasculitis; petechial hemorrhages in mucosae, musculature, and viscera; and sometimes glomerulonephritis. The condition usually is associated with *Streptococcus equi* infection of the upper respiratory tract. Serum of affected horses contains immune complexes of *S. equi*–specific antigens with equine IgA.[36] The glomerulonephritis sometimes seen with purpura has been attributed to deposition of similar immune complexes containing streptococcal antigens and IgG.[37]

1.2.3 Delayed Hypersensitivity Diseases

Documented immunologic characterization of delayed hypersensitivity conditions of the horse are lacking, although contact hypersensitivities have been reported in horses.[3] One well-characterized example of this type of condition is recurrent uveitis.

Equine recurrent uveitis, also known as moon blindness or periodic ophthalmia, is the most important cause of blindness in horses.[38] The disease results in acute and chronic ocular inflammatory disease, and chronic sequelae include development of posterior and anterior synechiae, cataracts, lens opacities, secondary glaucoma, and blindness. Eyes of affected horses contain IgG antibodies and autoreactive T cells specific for retinal anti gens.[39] A specific cause has not been identified. However, sensitization to a variety of pathogens, in particular to *Leptospira* spp.,[40,41] is thought to induce the immune-mediated pathologic response that is central to the disease.[42] Treatment with corticosteroids and other antiinflammatory agents is essential to avoid visual debility or blindness. However, treatment failures are common, and the disease frequently recurs with further ocular damage months after the initial event, commonly leading to euthanasia.[38]

The understanding of the immunological basis of equine recurrent uveitis has been extended by studies of the immunoregulatory events in the eyes of affected horses. The T lymphocytes that invade the iris and ciliary body during this disease produce a pattern of interferon-γ cytokine production typical of a TH1 response.[43] These studies indicate that equine recurrent uveitis is an example of a type IV hypersensitivity disease mediated by TH1 cells.

1.2.4 Autoimmunity

Although a number of equine diseases are considered to be autoimmune in origin, few have been extensively studied.[44] Much of the explanation given previously for the immunopathologies involved in hypersensitivity disease can be applied to autoimmune disease. Well-described equine autoimmune disorders include neonatal isoerythrolysis, alloimmune thrombocytopenia, and immune-mediated anemia of adults, which have characteristics of type II hypersensitivities.[45] Less well-described entities include systemic lupus erythematosus[46] and pemphigus foliaceus,[47] which have characteristics of type II and III hypersensitivity diseases. As described previously, equine recurrent uveitis appears to represent a type IV hypersensitivity, and some morphological and immunological evidence exists for similarly classifying cauda equina syndrome (polyneuritis equi).[48–50]

With the exception of a few conditions, such as neonatal isoerythrolysis and penicillin-associated hemolytic anemia, the cause of few autoimmune conditions is well understood. One exception, however, is the anemia that can develop following administration of human recombinant erythropoietin to horses.[51,52] Substantial evidence indicates that horses mount an antibody response to the exogenous erythropoietin that cross-reacts with the endogenous hormone, resulting in erythroid hypoplasia. The lesson of this example may be that in the modern world, with increasing availability of recombinant drugs that mimic natural biological compounds, one would do well to remember that the immune system has an exquisite ability to distinguish what is foreign and to reject it vigorously.

1.3

1.3—Immunodeficiency

D. Paul Lunn

David W. Horohov

Immunodeficiencies occur in primary and secondary forms and recently have been reviewed extensively.[1,2] Primary immunodeficiencies have a genetic basis, whereas secondary immunodeficiencies result from failure of passive transfer in foals, immunosuppressive infections or drug treatments, neoplasia, or malnutrition. Immunodeficiencies

can affect specific components of the immune system, such as the lymphoid or phagocytic system. Typically immunodeficiency is suspected in any of the following circumstances[3]:

1. Onset of infections in the first 6 weeks of life
2. Repeated infections that respond poorly to therapy
3. Infections caused by commensal organisms or organisms of low pathogenicity
4. Disease resulting from the use of attenuated live vaccines
5. Failure to respond to vaccination
6. Marked neutropenia or lymphopenia that persists for several days

Equine immunodeficiency is suspected most commonly for the first three reasons, that is, because of increased susceptibility to infections. The most common immunodeficiency recognized in clinical practice is failure of passive transfer in foals.[4–6] Other causes of immunodeficiency vary from well-defined clinical entities, such as severe combined immunodeficiency of Arabian foals,[7] to cases in which immunodeficiency is suspected on clinical grounds but the specific cause or nature of the problem is difficult or impossible to define.[8] Regardless of their cause, immunodeficiencies result in increased susceptibility to infections that respond poorly to appropriate therapy. Defects in antibody production tend to predispose horses to pyogenic infection, whereas deficiencies in cell-mediated responses lead to infections with organisms normally not pathogenic in horses, such as *Candida albicans, Cryptosporidium* spp., or adenovirus. When any immunodeficiency is suspected, specific diagnostic tests are indicated to define the deficiency. The aim of the next section is to identify tests clinicians can apply practically in such cases and to explain their merits and limitations.

TABLE 1.3-1 Components of the Immune System and Tests for Quantitative or Functional Analyses[*]

COMPONENT	QUANTITATIVE TESTS	FUNCTIONAL TESTS
Immunoglobulin	**Radial immunodiffusion, membrane ELISA,[†] electrophoresis, precipitation tests[‡]**	**Response to vaccination**
Lymphocytes	**Complete blood cell count, DNA-PK$_{CS}$ genetic evaluation,** [§] FACS analysis of lymphocyte subsets using monoclonal antibodies	**Response to vaccination, intradermal PHA test,** in vitro lymphoproliferation assays
Neutrophils and macrophages	**Complete blood cell count**	Chemiluminesence and bactericidal assays; flow cytometric evaluation of phagocytosis and oxidative burst
Eosinophils and basophils	**Complete blood cell count**	No commonly available tests
Complement	No commonly available tests	No commonly available tests
Acute phase proteins	Electrophoresis	No commonly available tests

* The table lists components of the immune system that can be evaluated in horses and appropriate tests for quantitative or functional analyses of each component. The list is not exhaustive and is restricted to tests of likely practical value for which normal data is available. Tests in boldface type are routinely available to clinicians.

† *ELISA,* Enzyme-linked immunosorbent assay; *DNA-PK*$_{cs}$, DNA-protein kinase catalytic subunit; *FACS,* fluorescence-activated cell sorter; *PHA,* phytohemagglutinin.

‡ For example, zinc sulfate turbidity and glutaraldehyde coagulation.

§ See the section on severe combined immunodeficiency for a description of DNA-protein kinase catalytic subunit genetic testing.

1.3.1 Tests of Equine Immune Function

Tests of components of the immune system (e.g., lymphocytes and immunoglobulins) generally can quantitate that component or measure its functional capacity. Table 1.3-1 identifies the components of the immune system that currently can be analyzed in this manner and lists the corresponding quantitative and functional tests. Table 1.3-1 also identifies those tests that are likely to be commercially available. Few of the functional tests described are available unless the clinician is able to identify a sympathetic and capable equine immunologic research 37
laboratory. Despite these limitations, the available tests permit the identification of many of the well-defined 38
causes of immunodeficiency in horses.

1.3.1.1 TESTS OF ANTIBODY-MEDIATED IMMUNITY

Some assays of B lymphocyte function and number are described next; however, the principal tests of humoral immunity are quantitative assays of immunoglobulin concentration and measurements of specific antibody responses to vaccination. The variety of classes of immunoglobulins in the horse is complex and was reviewed earlier in this chapter.[9] For practical purposes, this section generally focuses on immunoglobulin G (representing the combination of two subclasses: IgGa and IgGb), IgG(T), IgA, and IgM.

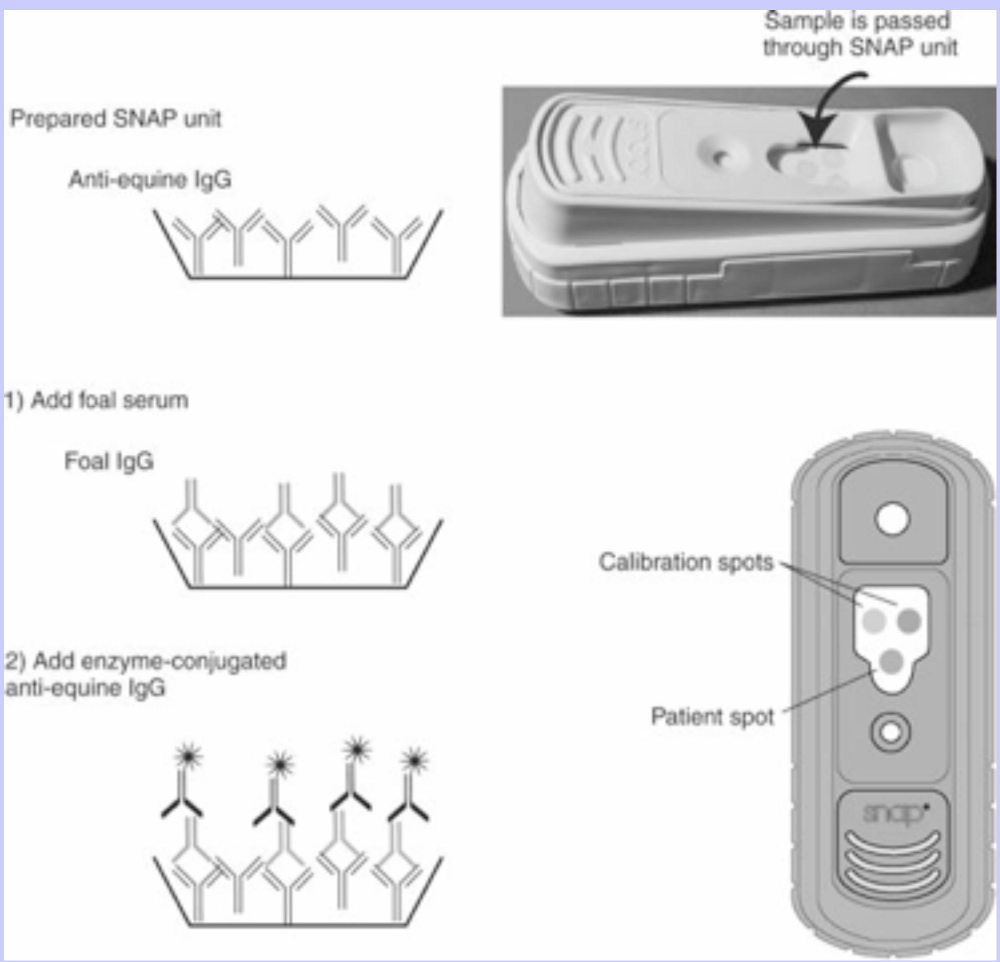
The current gold standard for measurement of concentrations of immunoglobulin classes is the radial immunodiffusion (RID) assay. The disadvantages of this test are cost and time required to perform the assay (24 hours), which makes it generally unsuitable for screening for failure of passive transfer of immunity in foals. Nevertheless, this form of test remains the single most valuable assay available to the clinician trying to measure total antibody concentrations in the horse. Currently, test kits are available for IgG, IgG(T), IgA, and IgM (VMRD Inc., Pullman, Washington). Specific IgG subclass RID tests—including IgGa, IgGb, IgGc, and IgG(T)—are available for research use (Bethyl Laboratories, Montgomery, Texas). The RID test is based on the ability of antigen and antibody to precipitate at equivalence when combined in proportion in agar gel plates. The serum being tested is added to punched-out wells in agar impregnated with antibody to the specific immunoglobulin class being measured and is allowed to diffuse outward and bind with the anti–class-specific antisera. A precipitate forms when equivalence is reached and the area within the precipitate ring is directly proportional to the concentration of the patient's immunoglobulin class. Normal ranges of serum immunoglobulin concentrations are typically provided with commercial kits, and normal serum, milk, and colostrum concentrations of equine immunoglobulins have been described in numerous published studies. These results have been summarized and are available in tabular form in two sources[10,11] and at the VMRD Web site *(http://www.vmrd.com/RID/Eridinf.htm)*. However, one should note that the original literature cited in developing these normal ranges typically was published 15 to 20 years ago. More recent studies of foal and

adult horse serum IgG and IgM concentrations using currently available RID assays measured considerably higher normal values in some instances.[12,13] In addition, an extensive study of immunoglobulin concentrations in adult and foal serum and nasal secretions and in colostrum and milk using an experimental monoclonal antibody–based system has been reported.[14]

The most common question that a clinician seeks to answer regarding the immune status of a horse is whether a foal has achieved adequate passive transfer of immunity. Whatever test is chosen should be able to distinguish serum concentrations of IgG of less than 200 mg/dl, 200 to 400 mg/dl, 400 to 800 mg/dl, and greater than 800 mg/dl to permit diagnosis of total or partial failure of passive transfer. The test should be rapid to allow early initiation of therapy. A variety of tests have been used for this purpose: zinc sulfate turbidity, latex bead agglutination tests, enzyme-linked immunosorbent assay (ELISA), turbidometric analysis, or glutaraldehyde coagulation.[15,16] Addition of serum to zinc sulfate solution causes precipitation of immunoglobulins, principally IgG. Although the degree of resultant turbidity is usually proportional to the IgG concentration, turbidity may be increased by hemolysis in the sample, poor operating conditions, and poor-quality reagents. In the glutaraldehyde coagulation test, glutaraldehyde forms insoluble complexes with basic proteins in the serum.[17] Gel formation in 10 minutes or less is equated with a serum IgG concentration of 800 mg/dl or greater, whereas a positive reaction in 60 minutes indicates at least 400 mg IgG/dl serum. Like the zinc sulfate turbidity test, hemolysis may cause overestimation of the IgG concentration. In the latex agglutination test (Foalcheck, Haver Mobay Corp., Shawnee, Kansas), the patient's serum is mixed with the antiequine IgG absorbed in latex particles. Macroscopic agglutination is proportional to serum IgG. Currently, for rapid diagnosis the most convenient test system may be membrane-filter–based ELISA systems (e.g., SNAP, Idexx, Westbrook, Maine; Figure 1.3-1). This test can be performed on site with whole blood. Tests such as the glutaraldehyde coagulation test are simpler and cheaper, although they have the disadvantage that serum is required. Although data suggests that the glutaraldehyde coagulation test may be more sensitive than membrane-filter ELISAs in detecting failure of passive tranfer,[16,18] particularly in differentiating normal foals (>800 mg/dl IgG) from partial failure of passive transfer (400 to 800 mg/dl), specificity can be poor. The latter problem affects many of the rapid diagnostic tests for failure of passive transfer, and a more extensive discussion of test selection for this condition is presented in the section covering this disease.

Alternative available tests that give information about serum immunoglobulin content include electrophoresis and immunoelectrophoresis. Immunoelectrophoresis can demonstrate the presence of all currently recognized equine immunoglobulin classes. However, the test has a poor sensitivity and gives no quantitative information, such as might be obtained from rocket electrophoresis.[19] Serum electrophoresis gives quantitative information 38
about albumin, α-, β-, and γ-globulin concentrations (Figure 1.3-2), and its utility is demonstrated in detecting 39
the monoclonal gammopathies that accompany plasma cell myelomata.[20] Nevertheless, in the diagnosis of immunodeficiencies, electrophoresis should be viewed as an adjunct to RID assays, which are superior in terms of specificity and sensitivity.

Figure 1.3-1 Membrane-based enzyme-linked immunosorbent assay system (SNAP, Idexx) for measuring serum immunoglobulin G concentration. The diluted test equine serum sample is applied to a "patient spot" on a membrane impregnated with a capture antibody recognizing equine IgG. Calibration spots corresponding to specific concentrations of equine IgG (400 and 800 mg/dl) are adjacent to the patient spot. An enzyme-conjugated second antibody against equine IgG is applied to the entire membrane, and finally the device is triggered to release an enzyme substrate that produces a colored reaction corresponding to the amount of enzyme-conjugated antibody on the membrane. By comparison with the calibration spots, the concentration of IgG in the test sample may be estimated.

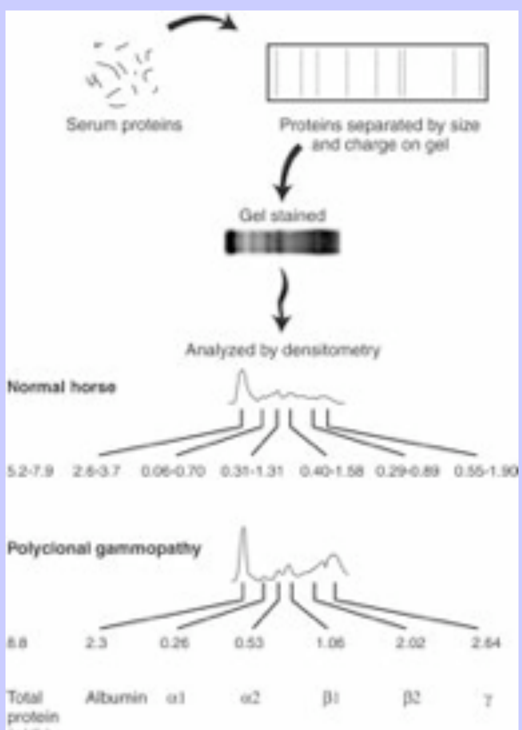


1.3.1.2 TESTS OF CELLULAR IMMUNITY

The simplest test of the cellular arm of the immune response is a total and differential white blood cell count, and this should be the starting point for any evaluation. Identification of an absolute lymphopenia, for example, is a critical finding in a suspected case of severe combined immunodeficiency (SCID) in an Arabian foal, although the result must be repeatable in a series of tests, given the variability of blood lymphocyte counts. Such a finding logically would lead to genetic testing to confirm the diagnosis.[7] The evaluation of a lymph node biopsy for normal architecture, including the presence or absence of cells in the B lymphocyte– or T lymphocyte–dependent areas, is another powerful test of the immune system. However, in profound immunodeficiencies such as SCID, lymphoid organs may be impossible to locate ante mortem. Beyond these readily available conventional techniques, three other more complex types of analysis can be valuable: flow cytometric analysis (primarily of lymphocytes, although other cell types can be analyzed), lymphocyte function testing, and functional analysis of phagocytic cells. 39

40

Figure 1.3-2 Serum protein electrophoresis. The complex mixture of serum proteins is separated by migration through an agarose gel slab in response to an electric field. Proteins are stained, and the intensity of staining of different bands is measured by densitometric scanning. These measurements are used to identify different types of globulins and albumin corresponding to stained bands.



1.3.1.2.1

Flow Cytometry

Taking the equine differential white blood cell count a step further is currently feasible because monoclonal antibodies are now available that can differentiate the morphologically identical equine lymphocyte family into distinct subsets with specific functions.[21] Many of these reagents and their sources are listed on the Equine Immunology Resources Web page: *http://www.vetmed.wisc.edu/research/eirh/home.html*. Flow cytometry allows rapid measurements to be made of individual cells in a fluid stream. Flow cytometers use lasers to measure multiple parameters including light scatter and fluorescence characteristics of cells and are complex instruments to construct, but the principles of their operation are simple (Figure 1.3-3). The fluidics system of the flow cytometer delivers cells one-by-one to a point in space intersected by a laser beam. The laser beam emits light of a defined wavelength to illuminate the cell, which results in scattered light of the same wavelength and fluorescent light of a different wavelength that is collected by photodetectors and converted into electronic signals.

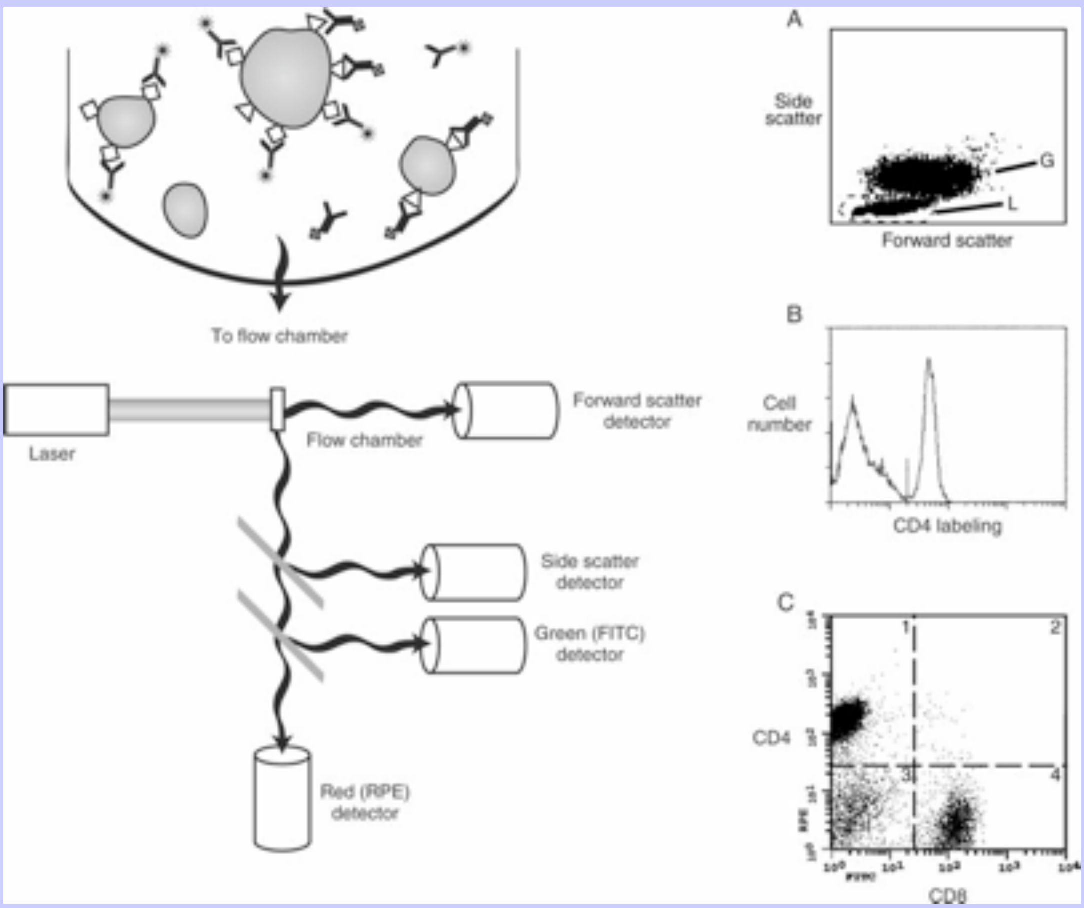
A forward collection lens collects light on the side of the flow chamber opposite the laser source. Light scattered from 1 to 20 degrees from the laser beam axis is collected as “forward scatter,” and the amount depends on the size of the cell being analyzed. Light scattered at 90 degrees (orthogonal) to the laser beam path is collected for the purpose of measuring “side-scatter” and fluorescent emission. Optical filtration separates scattered light and fluorescent light to permit independent measurement. Side scatter light depends on the granularity of cells. Fluorescent light can be detected independently for a number of fluorochromes of different wavelengths; typical examples include fluorescein and phycoerythrin.

Signals from the different detectors can be processed directly or after logarithmic amplification. The advantage of logarithmic amplification for the fluorescent signals is amplification of weak signals and compression of strong signals allowing their simultaneous display. By this means, signals with a 10,000-fold difference in intensity can be displayed. Signals typically are displayed as histograms or dual parameter correlated plots (dot plots), and statistical analysis is completed by computer. Histograms are analyzed by setting markers in particular channels. Dot plots are generated by drawing rectangular or polygonal boxes around data points. The software also allows the setting of gates for determining which events are collected or which events are to be included in later analyses. Typically these gating techniques use forward and side scatter to differentiate cell types, such as lymphocytes, monocytes, and granulocytes. The final key characteristic of flow cytometers is their capacity to analyze large numbers of events (cells) in a short time, making it possible to analyze many thousands of cells in a matter of seconds.

Figure 1.3-3 shows an example of such an analysis. In this instance the goal was to identify lymphocytes expressing the equine homologues of the CD4 and CD8 molecules using two monoclonal antibodies independently labeled with the fluorescein isothiocyanate (CD4) and phycoerythrin (CD8) fluorochromes. For this analysis a peripheral blood leukocyte population was prepared by simply lysing the erythrocytes in a blood sample using distilled water. Subsequently, the whole leukocyte population was stained in solution using the monoclonal antibodies. Alternatively, lymphocytes could have been purified from blood using
differential centrifugation techniques before staining. However, identical analytic results are obtained in the 40
horse using the more rapid technique of whole leukocyte preparation and exploiting the capacity of the flow 41
cytometer to distinguish lymphocytes from other cells.[22] During the flow cytometric analysis, the first step was to identify the lymphocytes using the forward and side scattering characteristics of different leukocyte populations. Part A of Figure 1.3-3 shows a dot plot of forward scatter versus side scatter, with each dot representing a cell. Granulocytes *(G)* can be distinguished from lymphocytes *(L)* by their greater granularity (side scatter) and size (forward scatter). The dotted line is a gate drawn around the lymphocyte population.

Subsequent analysis of fluorescence is directed only toward cells that fall within this gate. After establishing the physical characteristics of the cells to be analyzed, their fluorescence can be examined. In part B of Figure 1.3-3 a histogram depicts CD4 (fluorescein isothiocyanate) staining. A vertical marker identifies a gate set based on staining by a negative control antibody. Therefore all cells to the right of this marker are staining positively for CD4. For two-color staining, dot plots are again used. In part C of Figure 1.3-3, each dot represents a cell, and its position relative to the two axes illustrates its staining characteristics; the dotted lines represent the cutoff points for negative or positive staining. Therefore all cells in quadrants 1 and 2 are positively stained for CD4 and all cells in quadrants 2 and 4 are positively stained for CD8. Effectively, quadrant 1 contains all the helper T lymphocytes ($CD4^+$), quadrant 4 contains all the cytotoxic T lymphocytes ($CD8^+$), quadrant 3 contains the B lymphocyte population, and quadrant 2 is empty because no double-positive T lymphocytes are present in the blood of horses. The sum of the cells in quadrants 1 and 4 represents the T lymphocyte population.

Figure 1.3-3 Flow cytometric analysis (see text for key). *FITC,* Fluroscein isothiocyanate; *RPE,* R-phycoerythrin.



Flow cytometry has revolutionized immunobiologic studies in recent years, finding its most obvious clinical application in enumerating human $CD4^+$ lymphocytes in cases of acquired immune deficiency[23] and in 41
classifying leukemia and lymphoma.[24,25] A large number of antibodies are now available for use in the 42

horse,[21] and recent reports describe the use of flow cytometry to chart the response to microbial infection[12,26,27] and to differentiate equine leukemia.[25,28] Several recent studies provide examples of normal values for peripheral blood analysis.[12,13,29,30]

1.3.1.2.2 Lymphocyte Function Testing

Unfortunately, tests of lymphocyte function generally are limited in their availability in the field. In vitro tests of lymphocyte function include lymphocyte proliferation responses to mitogens such as pokeweed (B cell dependent), phytohemagglutinin (T cell dependent), or concanavalin A (T and B cell dependent). These assays are generally not commercially available, although they commonly are performed by immunologic researchers. In addition, some caution should be used because inferences about the intact animal drawn from the results of these in vitro tests may not always be valid.[3] Because of significant variability in results, performing parallel studies on suitable age-matched control horses is essential. The end point of these tests usually is read by determining the incorporation of radioactive tritium-thymidine into the total population of proliferating cells. Nonradioactive alternatives exist, and one strategy uses intracellular labeling of lymphocytes with 5-carboxyfluorescein diacetate-succinimidyl ester. Labeled cells fluoresce, and after subsequent divisions in response to mitogens, this fluorescence decreases by half for each cycle of cell division. Labeling allows for measurement of equine lymphocyte proliferation using flow cytometry, and simultaneous two-color staining allows for measurement of proliferation in specific lymphocyte subsets.[31]

Two tests that can be valuable and are readily available in practice are response to vaccination, as measured by rising serum titers, and response to intradermal phytohemagglutinin, which depends on a delayed-type hypersensitivity T lymphocyte response and develops in normal animals without prior sensitization.[32] A 50-μg dose of phytohemagglutinin in 0.5 ml of phosphate-buffered saline is injected intradermally, while 0.5 ml of phosphate-buffered saline is administered intradermally at a distant site. At the phytohemagglutinin site, an increase in wheal size of 0.6 mm or less indicates a defect in cell-mediated immunity. Response to vaccination has proved to be a potent means of identifying immunodeficiency in conditions such as juvenile llama immunodeficiency syndrome.[33] Similarly, the equine immune response to a polyvalent inactivated bovine vaccine has been used to document the immunosuppressive effects of corticosteroid administration.[34] For practical purposes, response to rabies or tetanus vaccination may be the most suitable available test provided that no routine vaccination had been administered in the immediate past. Equine rabies or tetanus antibody titer determination is typically commercially available, and the majority of available vaccines are sufficiently potent to provoke a fourfold increase in titer in normal horses.

1.3.1.2.3 Phagocyte Function Testing

Testing of equine neutrophil migration, phagocytic function, and bactericidal activity has been reported by several investigators.[35–38] The techniques used are typically only available in research laboratories and are not well adapted to investigations of individual animals unless adequate age-matched control animals also are examined. More quantitative information may be obtained by adapting assay systems to flow cytometric analysis. Two reports describe flow cytometric analysis of neutrophil phagocytosis of fluorescent microspheres[39] or yeast cells.[40] More recently, Raidal, Bailey, and Love[41,42] have described testing of alveolar macrophage and blood neutrophil phagocytic function using fluorescent-labeled bacteria and oxidative burst activity using oxidation of dichlorofluorescein. These flow cytometric approaches have great

promise, and have been applied to various studies including measurements of the effect of age[43–45] and of exercise[46] on neutrophil function.

1.3.2 Tests of Innate Immunity

Components of the innate immune response that have been measured in the horse include the numbers of granulocytes and monocytes in peripheral blood and their phagocytic function (see the previous discussion), natural cytotoxicity in terms of lymphokine-activated killer cell activity,[36,47,48] and measurement of soluble factors including several acute phase proteins[49–53] and complement. Equine complement activity can be measured using a hemolytic assay in which antibody-sensitized chicken erythrocytes are used as target cells, and the amount of serum required to lyse 50% of these targets is expressed as CH_{50} units.[54] More recently a flow cytometric assay has been described.[55] These tests have been used in some instances to detect relative immunodeficiency in terms of lymphokine-activated killer cell activity in exercised horses[48] or complement activity in foals.[56] Currently, these techniques have limited availability.

1.3.3 Primary Immunodeficiencies

1.3.3.1 SEVERE COMBINED IMMUNODEFICIENCY

SCID is a lethal primary immunodeficiency, affecting Arabian foals, human beings, mice, and dogs; characterized by failure to produce functional B and T lymphocytes; and resulting in lack of any antigen-specific immune responses.[1,57,58] The majority of affected foals are Arabians, in which the condition is 42
inherited as an autosomal recessive trait and results from a lack of DNA protein kinase activity that prevent 43
V(D)J recombination.[7,59] In studies conducted in the United States and reported in 1977, the incidence of SCID among Arabian foals was at least 2% to 3%,[60] suggesting a carrier prevalence rate between 25% and 26%. However, in more recent studies conducted in the United States using a precise molecular diagnosis of the carrier state, carrier prevalence was consistently 8%.[61,62]

1.3.3.1.1 Clinical Signs and Laboratory Findings

Affected foals are clinically normal at birth but develop signs of infection during the first 1 to 3 months of life. The age of onset of infection depends on the adequacy of passive transfer and degree of environmental challenge. As maternal antibodies are catabolically eliminated, foals with SCID are increasingly susceptible to infections with bacterial, viral, fungal, and protozoan agents. Bronchopneumonia is a prominent disease, often caused by adenovirus (which is the most significant pathogen of foals with SCID, affecting two thirds of all animals),[63] *Pneumocystis carinii,* or *Rhodococcus equi*. Enteritis, frequently caused by *Cryptosporidium parvum,*[64] arthritis, and omphalophlebitis are common. Adenoviral infection frequently extends to the gastrointestinal and urogenital systems and causes pancreatic disease leading to loss of endocrine and exocrine tissue and possibly contributing to the impaired growth and weight loss observed in foals with SCID.[1]

Clinical signs include nasal discharge, coughing, dyspnea, diarrhea, fever, and weight loss. Although antibiotics, plasma, and supportive care prolong the course of disease, death invariably occurs before 5 months of age. The only exception to this rule was a single foal experimentally treated with a bone marrow

transplant from a histocompatible donor. The foal lived until 5 years of age before dying of an unrelated cause.[65] A consistent hematologic finding is absolute lymphopenia (<1000 μ/L), with neutrophilia being a variable finding resulting from bacterial infection. Total serum globulins and serum IgG can be normal in the first weeks of life if passive transfer is adequate but decline as maternal immunoglobulins are catabolized. Normal foals synthesize IgM from 180 days of gestation and have detectable IgM at birth in presuckle samples, whereas foals with SCID have no IgM.[66] After colostral ingestion, SCID foals also have IgM, although with its relatively short half-life, IgM is undetectable by 2 to 4 weeks of age.[1]

1.3.3.1.2 Cause and Pathogenesis

Normal maturation of T and B cells requires rearrangement of a series of germ line genes to create genetic sequences that can encode the wide diversity of antigen receptors required by these lymphocytes (the T cell receptor or immunoglobulin antigen-binding sites, respectively, as described in Chapter 1.1). These genes are called the V, D, and J genes, and the overall process is called V(D)J recombination. This process depends on two groups of enzymes, the recombinase activating gene products, and DNA-protein kinase (DNA-PK), which is critical for DNA double-stranded break repair. In foals with SCID a component of DNA-PK called DNA-PK catalytic subunit (DNA-PK_{cs}) is defective, and consequently V(D)J recombination events do not occur, lymphocytes do not mature, and immature lymphocytes are eliminated.[7,59] The defect is a five nucleotide deletion in the DNA-PK_{cs} gene that produces a premature stop codon and prevents formation of the complete enzyme.

1.3.3.1.3 Diagnosis

Previously, antemortem diagnosis of SCID was suggested by appropriate clinical signs in a foal of Arabian breeding with persistent marked lymphopenia (usually <500/μL) and the absence of serum IgM by RID. If presuckle serum is unavailable for testing, serum IgM cannot be used as a diagnostic aid until the foal is older than 3 weeks. All suspected cases required confirmation by the necropsy finding of hypoplasia of the spleen, thymus, and lymph nodes with the absence of any normal lymphoid architecture. With the identification of the genetic defect causing SCID, the current standard for definitive diagnosis is demonstrating that the foal is homozygous for the defective SCID gene. This test depends on polymerase chain reaction amplification of a specific region of the DNA-PK_{cs} gene, and evaluation of the amplicon in a Southern blot using probes specific for normal and mutant sequences.[7] This test is commercially available (VetGen, Ann Arbor, Michigan), requires whole blood or cheek swabs, and can identify homozygous affected, heterozygous carriers, and normal animals.

1.3.3.1.4 Treatment

Supportive care may prolong the course of disease, but affected foals die by 5 months. Immunologic reconstitution is currently impractical and an ethically questionable procedure.

1.3.3.1.5 Client Education

Arabian mares and stallions intended for breeding should be tested for SCID carrier status. When two heterozygous carriers are bred, the progeny will include 25% foals with SCID, 50% carriers, and 25% homozygous normal foals. Therefore prevention of SCID requires identification of carriers and their removal

from the breeding population or breeding exclusively with homozygous normal animals and subsequent testing of progeny before their own breeding future is planned. 43

44

1.3.3.2 ANEMIA, IMMUNODEFICIENCY, AND PERIPHERAL GANGLIONOPATHY: FELL PONY IMMUNODEFICIENCY SYNDROME

In the late 1990s a new syndrome of anemia, immunodeficiency, and peripheral ganglionopathy was described in Fell pony foals.[67,68] Affected foals became ill within 2 to 3 weeks of birth and died by 3 months of age.

1.3.3.2.1 Clinical Signs and Laboratory Findings

Clinical signs include ill thrift, anemia, respiratory infection, glossal hyperkeratosis, and diarrhea. Anemia can be severe and is normochromic and normocytic to macrocytic, with small numbers of late erythroid precursors in bone marrow.[68,69] Some foals are affected by cryptosporidial enteritis and adenoviral bronchopneumonia and pancreatitis. Plasma protein concentrations and blood lymphocyte counts may be normal or decreased. T cell subsets measured by flow cytometry are normal, although expression of major histocompatibility complex II is low. In vitro lymphoproliferative responses are normal.[70] On necropsy, lymphoid organs can be small, and secondary lymphoid follicles and plasma cells are absent.[68] Neuronal changes are characterized by neuronal chromatolysis in the cranial mesenteric, dorsal root, and trigeminal ganglia.

1.3.3.2.2 Cause and Pathogenesis

Preliminary evidence indicates that Fell pony syndrome is a genetic disease inherited as an autosomal recessive trait, although the underlying defect is unknown (M. Holmes, personal communication, 2002).

1.3.3.2.3 Diagnosis

Confirmation of diagnosis depends on the presence of clinical signs in Fell pony foals and histologic confirmation of erythroid hypoplasia in the bone marrow, neuronal chromatolysis in peripheral nerve ganglia, absence of secondary lymphoid follicles, and low numbers of plasma cells in spleen and mesenteric lymph nodes.

1.3.3.2.4 Treatment

Treatment of specific infections is of limited efficacy in affected foals, particularly those affected by severe anemia and diarrhea, and all die by 3 months.

1.3.3.2.5 Client Education

Because the underlying basis of this disease is unknown, giving specific advice is difficult. If the condition is proved to be an autosomal recessive trait, then the dam and sire of affected foals will be confirmed as carriers and breeding should be avoided.

1.3.3.3 SELECTIVE IMMUNOGLOBULIN M DEFICIENCY

Selective IgM deficiency is characterized by substantially reduced or absent serum IgM with normal or increased concentrations of other immunoglobulins and no other evidence of immunodeficiency.[1,71] Serum IgM concentrations are more than two standard deviations below the mean of age-matched control animals. All other immunologic parameters are normal, although in one case a lack of response to lipopolysaccharide, a B cell mitogen, was reported.[72] The syndrome has been described most frequently in Arabians and Quarter Horses, although the diagnosis has been made in other breeds.

1.3.3.3.1 Clinical Signs and Laboratory Findings

Two clinical syndromes have been described. The first condition affects foals 2 to 8 months of age, which develop severe pneumonia, arthritis, and enteritis with or without septicemia. Many affected foals die before 10 months of age. Gram-negative bacterial infections are common (especially with *Klebsiella* species), and age at onset of signs is generally older than in foals with combined immunodeficiency. Some affected foals survive but have a history of repeated bacterial infections that respond temporarily to therapy but recur once antimicrobial therapy is discontinued. These foals grow poorly and generally die within 2 years. Foals rarely can recover from IgM deficiency, suggesting that such cases actually may be secondary rather than primary immunodeficiencies.[73]

The second presentation involves horses between 2 and 5 years of age, many of which have or ultimately develop lymphosarcoma. These individuals may have external or internal lymphadenopathy or both. Chronic weight loss, depression, and other nonspecific signs usually accompany lymphosarcoma. In cases associated with lymphosarcoma, the IgM deficiency is presumed to be a secondary rather than a primary immunodeficiency.

Routine laboratory findings are not diagnostically specific. Hematologic abnormalities consistent with chronic inflammatory disease, such as anemia, neutrophilia, and hyperfibrinogenemia, are commonly present. The total plasma protein and serum globulin concentrations are usually normal.

1.3.3.3.2 Cause and Pathogenesis

Although a genetic basis is suspected, the pathogenesis of selective IgM deficiency is unknown.[1] Primary and secondary forms of this syndrome seem likely to exist.

1.3.3.3.3 Diagnosis

Definitive diagnosis of selective IgM deficiency is made by measuring the major serum immunoglobulins by RID and determining the absolute lymphocyte count. Horses with selective IgM deficiency have serum IgM concentrations persistently less than two standard deviations below that of age-matched controls (<15 mg/dl at 4 to 8 months; <25 mg/dl at >8 months) coupled with normal concentrations of IgG (≥400 mg/dl) and a 44
normal lymphocyte count. Because seriously ill foals may have transiently depressed serum IgM 45
concentration, suspected cases of deficiency should be tested at least twice to document that IgM concentrations remain low. All other immunoglobulin concentrations are normal.

1.3.3.3.4

Treatment

Other than supportive care and antimicrobial therapy, no treatment is effective for selective IgM deficiency. Transfused plasma concentrations of IgM are low and the half-life is short, thus any benefit would be only temporary.

1.3.3.3.5

Client Education

The prognosis must be guarded; however, recovery has been reported.[73] Because primary immunodeficiency is likely in foals affected during the first year of life, remating the sire and dam may be inadvisable.

1.3.3.4

OTHER PRIMARY IMMUNODEFICIENCIES

Transient hypogammaglobulinemia and agammaglobulinemia are reported as established primary immunodeficiency syndromes in horses. However, these conditions have been reported infrequently and consequently remain poorly defined. The available information follows. Another form of immunodeficiency affecting humoral immunity was described by Boy, Zhang, Antczak et al.[74] in a 10-month-old Arabian colt. The horse exhibited an absence of serum IgM, IgA, and IgG(T) and a normal concentration of IgG. In vitro testing of peripheral blood mononuclear cells with T cell mitogens elicited normal responses, whereas responses to B cell mitogens were weak. On postmortem examination lymphoid organs showed generalized lymphocyte depletion.

To increase the understanding of these and other currently unidentified immunodeficiency syndromes of horses, it is critical that every effort be made to identify such cases and thoroughly investigate them. Newly available immunologic resources may make further defining of these diseases possible and increase the diagnostic and prognostic resources, provided case material is identified.

Transient hypogammaglobulinemia has been reported in only two foals, an Arabian and a Thoroughbred, and is characterized by delayed onset of immunoglobulin synthesis.[73,75] Affected foals manifest signs consistent with bacterial and viral infections when passively acquired immunoglobulins are catabolized to nonprotective concentrations. For unknown reasons the onset of autologous immunoglobulin production, which generally occurs at birth, is delayed until these foals are approximately 3 months of age. Hematologic studies may suggest chronic infection, although total plasma protein is normal or slightly reduced. Diagnosis is based on the presence of low serum IgG (<200 mg/dl) and IgG(T) (<20 mg/dl) at 2 to 4 months of age, with low-normal serum IgM (>15 mg/dl) and IgA (>20 mg/dl). Lymphocyte counts are normal. Antimicrobial therapy and plasma transfusions are necessary to minimize infections. Affected foals usually survive if they have not suffered failure of passive transfer concomitantly and they receive appropriate support between 2 and 4 months of age. The fact that foals spontaneously recover from this condition raises the question of whether the immunodeficiency may be secondary.

Agammaglobulinemia is characterized by absence of B lymphocytes and failure to produce immunoglobulins in the presence of normal cell-mediated immunity.[1] The disease has been described in five colts of Thoroughbred, Standardbred, or Quarter Horse breeds.[73,76,77] Clinical signs commence between 2 and 6 months of age and result from bacterial infections such as pneumonia, enteritis, and arthritis. Multisystemic infections that respond poorly to therapy are common, and laboratory changes reflect chronic inflammatory disease. The fact that this

syndrome has been described only in colts suggests an x-linked mode of inheritance, as occurs in a similar disease of human beings. A maturation defect from stem cells to B cells has been suggested.[1] Affected foals have persistently subnormal serum concentrations of all immunoglobulin classes and normal lymphocyte counts. Serum IgM and IgA are generally absent at the time of evaluation, and maternally derived IgG and IgG(T) decline with time. At 2 months of age, IgG is less than 300 mg/dl, declining to less than 100 mg/dl by 6 months. No serologic response to immunization occurs, and B lymphocytes, as determined by immunofluorescence, are absent. Tests of cell-mediated immune function such as intradermal phytohemagglutinin and in vitro blastogenesis are normal. Plasma and antimicrobial therapy only result in transient improvement. Affected horses die from disseminated infection between 1 and 2 years of age.

1.3.4 Secondary Immunodeficiencies

1.3.4.1 FAILURE OF PASSIVE TRANSFER

Failure of passive transfer is the most common immunodeficiency disorder of horses and recently has been reviewed extensively.[2] The condition occurs in all breeds secondary to inadequate absorption of colostral antibodies. Failure of passive transfer is correlated significantly with increased susceptibility to infectious disease and death in neonatal foals.[78,79] The newborn foal is capable of mounting a normal immune response, as described in Chapter 1.1. However, neonatal foals are immunologically naïve and thus have not yet developed memory responses or produced antigen-specific antibody and other forms of adaptive immunity. 45
During the first 1 to 2 months of life, foals depend on passively transferred immunity for protection from 46
infectious disease. The diffuse epitheliochorial nature of the equine placenta does not allow for in utero immunoglobulin transfer to foals. Although minor concentrations of some immunoglobulins can be detected at birth, the foal is born essentially agammaglobulinemic and acquires passive immunity by the ingestion and absorption of colostrum from the dam.[80,81] Colostrum is a specialized form of milk containing immunoglobulins that are produced during the last 2 weeks of gestation under hormonal influences. Colostrum contains primarily IgGa, IgGb (IgGa plus IgGb is the equivalent of IgG), and IgG(T), with smaller quantities of IgA and IgM, all of which have been concentrated into mammary secretions from the blood of the mare.[14,82] Colostrum is produced only one time each pregnancy and is replaced by milk that contains negligible immunoglobulins within 24 hours of the initiation of lactation.[14,82,83] Normal foals suckle within 1 to 3 hours of birth. The absorptive capacity of the foal's gastrointestinal tract for immunoglobulins is greatest during the first 6 hours after birth and then steadily declines until immunoglobulins can no longer be absorbed when the foal is 24 hours old. The incidence of failure of passive transfer is highly variable among groups of horses and seems to depend primarily on management factors that ensure early colostral ingestion.[84] The reported prevalence of at least partial failure of passive transfer ranges from 3% to 37%.[18,73,78,84]

1.3.4.1.1 Clinical Signs and Laboratory Findings

Failure of passive transfer does not cause any clinical signs of disease directly. Failure of passive transfer is suspected when signs of generalized or localized bacterial infections such as septicemia, pneumonia, enteritis, and arthritis develop during the first 3 weeks of life. Routine laboratory findings may suggest sepsis, but the presence of infection in the neonatal period is not pathognomonic for failure of passive transfer. Common abnormalities include neutropenia or neutrophilia, hypoglycemia, and hyperfibrinogenemia. The total plasma protein may be low, normal, or increased in foals with failure of

passive transfer because of the wide variation in normal presuckle total plasma protein and the confounding effects of dehydration secondary to sepsis.

1.3.4.1.2 Cause and Pathogenesis

Causes for failure of passive transfer in foals include (1) failure of the foal to ingest an adequate volume of colostrum in the early postpartum period; (2) loss of colostrum via premature lactation; (3) inadequate immunoglobulin content of the colostrum; and (4) insufficient immunoglobulin absorption via the intestine.[2,85] A high negative correlation exists between foal serum IgG concentration and the incidence of severe infections[78]; however, the minimum amount of IgG necessary for protection of a foal from infection varies with the amount and virulence of environmental pathogens, concomitant stress factors, and colostral antibody titer against specific pathogens. Although a serum IgG concentration of at least 400 mg/dl has been considered evidence of adequate passive transfer, most normal foals attain values more than twice this high,[78,84] and serum IgG greater than 800 mg/dl may be required for adequate immunity.[79] Numerous other colostral factors may be important for the immune protection of foals. Colostrum has been shown variously to regulate cell-mediated immunity, activate granulocytes, promote intestinal absorption of macromolecules, decrease intestinal colonization by pathogens, and contain constituents of innate immunity (e.g., lactoferrin and complement) and leukocytes that have a local protective role in the neonatal digestive tract and may be absorbed systemically.[86,87] At this time the significance of these various phenomena for the health of neonates and their immunologic development is largely unknown. The one exception is the finding that colostral ingestion suppresses de novo antibody responses in foals in a nonspecific and an antigen-specific manner.[83,88]

Neonatal weakness and lack of maternal cooperation (common in maiden mares) are common reasons for the foal to ingest an inadequate volume of colostrum. If colostral ingestion is delayed beyond 6 hours, the absorption of immunoglobulins is reduced significantly. Lactation before parturition is another common reason for failure of passive transfer, because colostrum is only produced one time each gestation. The causative factors for premature lactation are unknown at this time, but foals from mares that “leak” milk hours to days before parturition are likely to suffer failure of passive transfer.[85]

Subnormal colostral immunoglobulin content (<3000 mg/dl) is rare in mares that do not prelactate,[84] but wide individual variation in colostral concentration of immunoglobulins does occur.[84,89–91] Poor-quality colostrum undoubtedly may cause failure of passive transfer. Colostral immunoglobulin content can be estimated by specific gravity or quantitated by RID.[85]

Malabsorption is implicated as a cause of failure of passive transfer when foals are known to have ingested an adequate volume of good-quality colostrum within 12 hours of birth. Because glucocorticoids hasten the maturation of specialized enterocytes, stress-causing endogenous corticosteroid release may cause reduced immunoglobulin absorption. However, obvious stress factors often are not found in foals with apparent impaired ability to absorb IgG.[6]

1.3.4.1.3 Diagnosis

Subnormal serum IgG concentration 24 hours after birth is the basis for diagnosis of failure of passive 46
transfer. Serum IgG of less than 200 mg/dl indicates complete failure of passive transfer, whereas 200 to 800 47
mg/dl should be considered partial failure of passive transfer. Many foals under good management

conditions may remain healthy if the serum IgG is at least 400 mg/dl, and consequently this cutoff point is measured by several rapid diagnostic tests. The most quantitatively accurate method to determine serum IgG is the single radial immunodiffusion test (VMRD Inc.); however, this assay is time-consuming and expensive and thus inappropriate for the diagnosis of failure of passive transfer when timely therapeutic intervention is paramount.[92] Numerous field screening procedures for IgG have been evaluated.[2,16,18,92] Criteria for selecting a screening test for equine failure of passive transfer must include accuracy, the time necessary to perform the test, ease of performance, and cost. Although the zinc sulfate turbidity and glutaraldehyde coagulation tests are inexpensive and provide results within 1 hour, the ease and reported accuracy of membrane-based ELISAs frequently make them the test of choice in many practice situations. However, results of a recent study suggest that the choice of screening test is not so straightforward. McClure, DeLuca, and Miller[18] evaluated the recently withdrawn CITE test (Idexx), the SNAP test (Idexx) (both membrane-based ELISA systems), a latex agglutination test (Foalcheck), the glutaraldehyde coagulation test, and the modified zinc sulfate turbidity test; all results were compared with an RID test. Serum from 203 foals at 24 to 72 hours of age was evaluated. The prevalence of failure of passive transfer at serum IgG concentration of less than 400 mg/dl was 22% and at less than 800 mg/dl was 37%. The withdrawn CITE test and the latex bead agglutination test were judged unsuitable for use as screening tests because of sensitivities of 52% and 53% for IgG less than 400 mg/dl. The most sensitive tests were the modified zinc sulfate turbidity and glutaraldehyde coagulation tests (95% and 89%, respectively, for IgG <400 mg/dl; 100% and 97%, respectively, for IgG <800 mg/dl). The modified zinc sulfate turbidity and glutaraldehyde coagulation tests were specific for complete failure of passive transfer but were less so for partial failure (80% and 91%, respectively, for IgG <400 mg/dl; 59% and 57%, respectively, for IgG <800 mg/dl). In comparison, the SNAP test was less sensitive (76% for IgG <400 mg/dl; 88% for IgG <800 mg/dl), but more specific (95% for IgG <400 mg/dl; 91% for IgG <800 mg/dl). These data highlight the difficulty faced by equine clinicians in selecting a rapid diagnostic test for failure of passive transfer. Because failure to diagnose and treat the condition could result in death of many foals, a sensitive test is required. However, specificity is also important, particularly given the cost of treatment (plasma transfusion) and the fact that treatment is not without its own inherent complications. These data suggest that no clearly superior test exists, comparing the modified zinc sulfate turbidity, glutaraldehyde coagulation, and SNAP tests. Individual clinician judgment is therefore important in test selection, although at this time the relatively good performance of the SNAP test and its convenience may continue to make it a popular choice. These data confirm that in general all screening tests are accurate in identifying foals with complete failure of passive transfer; however, variation exists in their ability to detect marginally deficient foals.[2]

1.3.4.1.4 Treatment

If failure of passive transfer is anticipated because of premature lactation, neonatal weakness, dam death, or low-specific-gravity colostrum, an alternative colostral source may be given orally. A minimum of 2 L of equine colostrum given in 500-ml increments during the first 8 hours after birth is optimal. Bovine colostrum may be substituted safely if equine colostrum is not available[56,93]; however, foals given bovine colostrum also may require plasma transfusion because bovine immunoglobulins have a short half-life in foals and are not specifically directed against equine pathogens.

If a foal is more than 12 hours old when failure of passive transfer is suspected or diagnosed, an intravenous plasma transfusion is indicated. Numerous commercial sources of equine plasma are available (Lake Immunogenetics, Ontario, New York; Veterinary Dynamics Inc., Chino, California; Ameri-Vet Labs, Addison, Illinois). Use of these products is convenient, saves time, and is safe because donors are free of alloantibodies and negative for infectious diseases. The only potential drawback to the use of commercial

plasma is that antibodies specific for pathogens in the environment of the foal may be lacking. Optimal plasma would be obtained from a local blood-typed donor, known to lack serum alloantibodies and alloantigens Aa and Qa. The volume of plasma necessary to bring serum IgG into an acceptable range cannot be predicted accurately because the volume depends on the severity of failure of passive transfer, the immunoglobulin content of the plasma, and on concomitant diseases, which may hasten immunoglobulin catabolism. Generally, 1 L of plasma increases the serum IgG concentration of a 50-kg foal by 200 to 300 mg/dl,[38] thus 2 to 4 L may be necessary to achieve a serum IgG concentration greater than 800 mg/dl. A therapeutic dose of plasma should be administered, and then foal serum IgG should be remeasured. If the desired concentration has not been attained, more plasma is necessary. Some foals with partial failure of passive transfer (IgG >400 and <800 mg/dl) may do well without plasma therapy if no preexisting infections exist and exposure to pathogens is minimized. These foals should be monitored closely for the development of infections. 47

48

1.3.4.1.5

Client Education

The prognosis for foals with failure of passive transfer depends on the degree of failure, the environment to which the foal is exposed, the age of the foal at the time of diagnosis, and the presence and severity of secondary infections. Management factors that ensure the ingestion of at least 2 L of high-quality colostrum within 6 hours of birth are paramount to prevent failure of passive transfer. Foaling should be witnessed so that any mispresentations can be corrected, and foals that do not nurse readily within 3 hours can be given colostrum via nasogastric tube. The evaluation of colostral specific gravity with a hydrometer (Lane Manufacturing, Denver, Colorado) may aid in predicting failure of passive transfer.[85] A colostral specific gravity of 1.060 corresponds to approximately 3000 mg/dl IgG, which is the minimum acceptable value. When dam colostral specific gravity is less than 1.060, some degree of failure of passive transfer should be suspected in the foal and corrected. Routine screening of foal serum IgG at 24 to 48 hours after birth allows necessary plasma therapy before the onset of infections.

Foals that are born prematurely, weak, or from prelactating mares should be provided with an alternative colostral source within 6 hours of birth. A colostrum bank can be established by collecting and freezing (−20°C) 250 ml of colostrum from mares that have not prelactated within 6 hours of foaling, once their own foals have suckled. Ideally, banked colostrum should be screened for alloantibodies, although they are unlikely if the mare's own foal remains healthy. The immunoglobulins in banked frozen colostrum are stable for at least 1 year.

1.3.4.2

EXERCISE

When conducted at a stressful level, exercise can affect equine immune function significantly.[94] Strenuous exercise significantly suppresses lymphoproliferative responses and increases lymphokine-activated killer cell activity.[48,95] In race horses, decreased lymphoproliferative responses can be demonstrated 12 to 16 hours after racing.[96] Protracted high-intensity training results in decreased phagocytosis and oxidative burst activity in neutrophils and lymphocytes, although pulmonary alveolar macrophage function is unaffected.[46] Other studies have demonstrated decreased neutrophil and pulmonary alveolar macrophage function in response to single bouts of intense exercise.[97,98] In unconditioned ponies, strenuous exercise increases susceptibility to experimental infection with equine influenza virus.[99,100] In an influenza infection study in trained horses, moderate exercise led to increased signs of clinical disease, although duration of disease was unaffected.[100]

Overall these various studies have demonstrated a clear immunomodulatory effect of exercise, with some specific evidence for increased susceptibility to infectious disease. Although this remains an active area of investigation with much to be learned, clearly the potentially immunosuppressive effect of high-intensity exercise, particularly of protracted duration or in unconditioned animals, needs to be recognized.

1.3.4.3 AGE

The high incidence of *respiratory infections in foals and weanlings,* which frequently relapse on cessation of antibiotic treatment,[101] has led to speculation that this condition results from immunodeficiency.[8] Although this possibility exists, another possibility is that the normal level of immunocompetence in this age group leads to increased susceptibility to pyogenic respiratory infections, particularly under group housing conditions. Features of the immune system of the foal that may predispose to such infections are discussed elsewhere in this chapter.

Old age has the potential to result in relative immunodeficiency, although few equine studies have investigated this possibility. Older horses display decreased lymphoproliferation to mitogens,[102] and in an exercise study they demonstrated reduced immunologic response to exercise.[95] The implications of such phenomena for disease risk in older horses remains uncertain. The high incidence of pituitary dysfunction in older horses is a risk factor for infectious disease, possibly as a consequence of high steroid levels.

1.3.4.4 LEUKOPROLIFERATIVE DISEASE–ASSOCIATED IMMUNODEFICIENCY

Lymphosarcoma often is associated with IgM deficiency[2] and also can be associated with decreased lymphocyte blastogenesis.[103,104] Affected horses were diagnosed with bacterial pneumonia in some instances, and in another report a horse suffering from myelomonocytic leukemia was found to be suffering from pulmonary aspergillosis.[105] These cases demonstrate the importance of considering leukoproliferative disease, and particularly lymphosarcoma, in cases of persistent infections that are refractory to treatment.

1.3.4.5 DRUG-INDUCED IMMUNODEFICIENCY

The most common iatrogenic cause of immunosuppression is corticosteroid treatment, often given with the specific aim of treating a hypersensitivity disorder. The mode of action and the effects of corticosteroids are reviewed in Chapter 1.4, but evidence exists for the capacity of corticosteroids to induce recrudescence of viral diseases such as equine infectious anemia[106] or equine herpesvirus 1 infection[107] and to lead to development of life-threatening bacterial infection.[108] Evidence also indicates that corticosteroid treatment can bias adaptive immune responses to vaccination in horses, specifically suppressing IgGa and IgGb responses without affecting 48
IgG(T) responses.[34] This phenomenon may be consistent with the capacity of corticosteroids specifically to suppress T helper cell type 1 immune responses without affecting T helper cell type 2 responses.[109,110] 49

1.3.4.6 INFECTIOUS DISEASE

Several infectious diseases have been associated with immunodeficiency in horses. The best characterized example may be *perinatal equine herpesvirus 1 infection.*[111] Foals infected with equine herpesvirus 1 late in gestation often are born weak with interstitial pneumonia and develop a variety of bacterial diseases.[112]

Affected foals have profound lymphopenia and generally die, despite therapy. The immunodeficiency is thought to be caused by viral-induced lymphoid damage, because necropsy reveals significant necrosis of lymphoid tissue in the thymus, spleen, and lymph nodes.

1.3.4.7 UNDIFFERENTIATED IMMUNODEFICIENCIES

A group of foals with *oral candidiasis* and *bacterial septicemia* between 2 weeks and 4 months of age had laboratory or histologic evidence of immunodeficiency that did not fulfill diagnostic criteria for any of the recognized primary immunodeficiencies.[113] Oral lesions ranged from focal white plaques on tongue margins to a generalized thick, white pseudomembrane covering the tongue and gingiva. Affected foals exhibited bruxism, ptyalism, fever, and depression in addition to pneumonia, arthritis, and diarrhea. The lymphocyte counts of affected foals were usually normal. Several foals had IgM deficiency coupled with depressed blastogenesis, suggesting cellular immune dysfunction. Many of the foals had low or marginally decreased serum IgG in addition to IgM deficiency or reduced blastogenesis. Whether the immunologic defects were primary or secondary was not determined. All foals died despite extensive therapy with parenteral antimicrobials, topical antimycotics, and intravenous plasma.

Acquired immunodeficiency was identified in a 7-year-old Appaloosa gelding with no history of previous illness.[114] Clinical signs included lethargy, anorexia, and dyspnea. Pneumonia and septicemia caused by *Rhodococcus equi* were confirmed by tracheal wash and blood culture, respectively. Immunologic evaluation revealed significant lymphopenia, subnormal serum IgG and IgA with marginally low IgG concentrations, failure to respond serologically to immunization, and reduced in vitro lymphocyte blastogenesis. Histologic examination of lymph nodes and spleen revealed lymphoid atrophy.[97,98]

1.4

1.4—IMMUNOMODULATORS

D. Paul Lunn

David W. Horohov

Clinicians frequently seek to increase normal, restore deficient, and temper overexuberant host immune responses. For these reasons, modulation of the immune system, which provides critical defense against many types of disease, has become an area of intense interest in clinical medicine. Immunostimulants and immuno depressants are considered immunomodulators. A variety of ways exist to classify immunomodulators beyond this distinction, but for practical purposes they may be classified best based on their origin, that is, physiologic products (actual normal components of the immune response), microbial products, and chemically defined agents. Immunomodulation also can result from modes of therapy not considered in this chapter, including bone marrow transplantation and irradiation.

Although a scientific rationale for the use of immunomodulators exists, a major limitation is the complexity of the immune response to be modulated. Clinicians face several major problems in the rational clinical application of immunomodulators. Current diagnostic methods do not allow precise identification of the in vivo defects, deficiencies, or excesses of substances or regulators present within the immunoregulatory network. Consequently, attempts to intervene with immunomodulators often are crude and nonspecific. Some of the information on which the use of immunomodulators is based has come from controlled experimental studies, some performed in vitro and others in vivo. In clinical patients, expectations based on these types of studies frequently are not realized. Reasons

for this include the timing of the administration of the immunomodulator during the course of disease and the fact that observation of a single immunological phenomenon resulting from use of an immunomodulator, for example, an increase in lymphocyte count or lymphoproliferative responses, does not necessarily translate into improved clinical performance with an infectious disease. Because of the complexity of the immune network, the rational use of immunomodulators can be considerably more difficult than the use of antimicrobial agents. An example of the importance of timing in immunomodulatory intervention is the success of immunosuppressive therapy in the context of organ allografts compared with the frequent treatment failures experienced in treating autoimmune disease. In the former case, therapy is planned in advance of introducing the allograft, whereas in the latter case the immune response and resulting disease are well established before they are detected and therapy is initiated.

Immunomodulators have been embraced by clinicians with great enthusiasm, and the concept of their use remains appealing.

1.4.1 Immunosuppressors

1.4.1.1 CORTICOSTEROIDS

Corticosteroids are classic examples of immunosuppressive agents. Corticosteroids exhibit an extensive range of effects on elements of the innate (inflammatory) and adaptive immune responses. The mechanism of action of corticosteroids is illustrated in Figure 1.4-1. Corticosteroids, acting through their cytoplasmic steroid receptors, directly regulate as many as 1% of genes in the genome, usually resulting in induction of transcription.[1] Table 1.4-1 summarizes the useful antiinflammatory effects of corticosteroids. The effect on the adaptive immune response is complex.[2] For example, in cases of autoimmune disease such as autoimmune hemolytic anemia, corticosteroids may act by reducing phagocytosis of antibody-coated cells by the 52
reticuloendothelial system rather than decreasing antibody production. Nevertheless, corticosteroids have been 53
shown to have effects on antibody production, and in the horse they can suppress de novo antigen-specific immunoglobulin Ga (IgGa) and IgGb responses while sparing IgG(T) responses.[3] Such suppression may be consistent with the action of corticosteroids to suppress type 1 T helper cell responses while sparing type 2 T 53
helper cell responses.[4–7] Cell migration is affected significantly by corticosteroids, and in the horse, 54
corticosteroids suppress neutrophil migration and phagocytic and bactericidal activity.[8] The mechanism whereby migration is decreased involves decreased expression of integrin molecules including selectins and integrins.[9]

Figure 1.4-1 Lipid-soluble corticosteroid molecules diffuse across the plasma membrane into the cytosol and bind to steroid receptors. This displaces a heat-shock protein (Hsp90) normally bound to the nascent steroid receptor, exposing a DNA-binding region. The new complex enters the nucleus and binds to specific regulatory DNA sequences, resulting in modulation of transcription of a wide variety of genes.

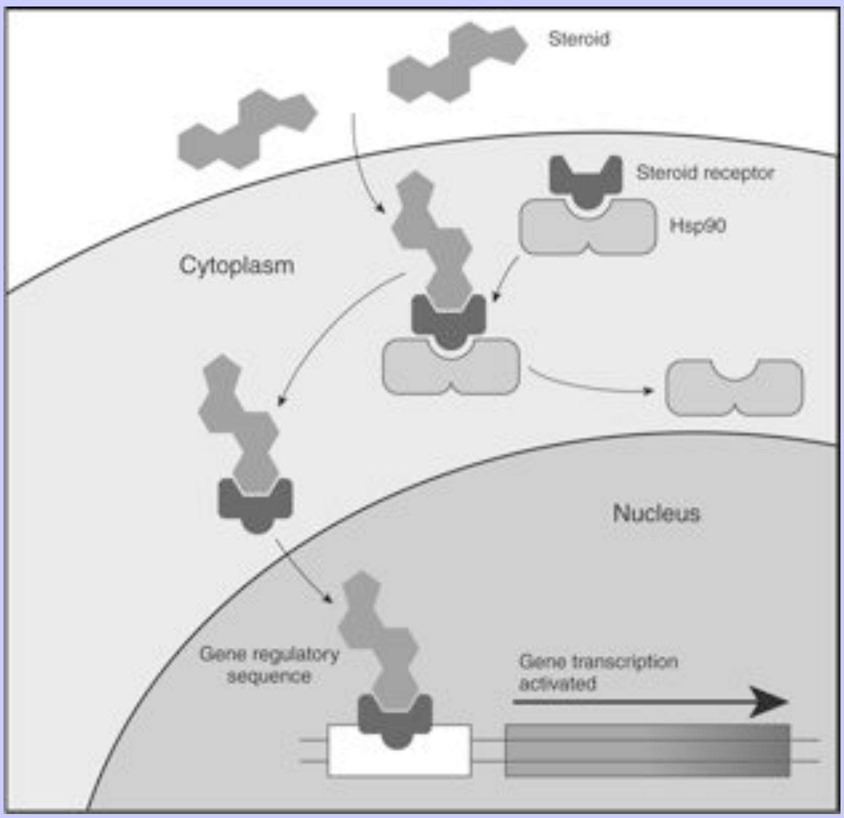

TABLE 1.4-1 Antiinflammatory Effects of Corticosteroid Therapy Mediated by Regulation of Gene Transcription

ACTION OF CORTICOSTEROIDS	
DIRECT EFFECT	**PHYSIOLOGIC EFFECTS**
Decrease IL-1, TNF-α, GM-CSF, IL-3, IL-4, IL-5, and IL-8.	Decrease inflammation caused by cytokines.
Decrease NOS.	Decrease NO.
Decrease phospholipase A_2 and cyclooxygenase type 2. Increase lipocortin-1.	Decrease prostaglandins and leukotrienes.
Decrease adhesion molecules.	Decrease emigration of leukocytes from vessels.
Increase endonucleases.	Increase apoptosis in lymphocytes and eosinophils.

From Janeway CA Jr, Walport M et al: *Immunobiology: the immune system in health disease,* ed 5, 2002. Reproduced by permission of Routledge/Taylor & Francis Books, Inc.

IL, Interleukin; *TNF,* tumor necrosis factor; *GM-CSF,* granulocyte-macrophage colony-stimulating factor; *NOS,* nitric oxide synthase; *NO,* nitric oxide.

Although corticosteroids are powerful immunosuppressive agents, they also may predispose patients to life-threatening opportunistic infections[10] or recrudesence of viral infection.[11–13] Additional extensive undesirable side effects include fluid retention and decreased wound healing. For this reason, prolonged or high-dose corticosteroid therapy must be used judiciously.

1.4.1.2 CYTOTOXIC DRUGS

The two commonly used immunosuppressive cytotoxic drugs, *azathioprine* and *cyclophosphamide,* interfere with DNA synthesis and act primarily on dividing cells.[1] This activity is useful for treating cancer and for suppressing dividing lymphocytes. Toxicity limits the use of these drugs, although at lower doses they can be used in combination with corticosteroids. Two case reports describe the use of these drugs, with some success, in horses suffering from immune-mediated hemolytic anemia or thrombocytopenia when corticosteroid therapy alone had failed.[14,15]

1.4.1.3 BACTERIAL AND FUNGAL DERIVATIVES

This class of drugs includes relatively nontoxic alternatives to immunosuppressive cytotoxic drugs. *Cyclosporine* is a fungal derivative and has emerged as a major immunosuppressive agent for allograft survival. The drug selectively inhibits proliferation, cytotoxicity, and lymphokine production of T cells by binding to intracellular proteins known as immunophilins and by interfering with signaling pathways that are important for clonal expansion of lymphocytes.[1] Cyclosporine is efficacious in suppressing specific immune responses with minimal nonspecific toxic effects on polymorphonuclear leukocytes, monocytes, and macrophages. Thus immunosuppressed patients suffer fewer severe secondary infections. The drug is not hazard free; in addition to suppressing lymphocyte responses in general, cyclosporine is also toxic to the kidneys and other organs.

In horses the use of cyclosporine has been limited to topical therapy for ocular inflammatory disease, including keratitis[16] and uveitis.[17] In the treatment of uveitis, cyclosporine treatment suppressed the numbers of infiltrating T lymphocytes and the interleukin-2 and interferon-γ levels.[18]

1.4.2 Immunostimulants

Although the clinical value of immunosuppressive drugs such as corticosteroids and immunostimulant adjuvants in vaccines clearly is established, evidence for the clinical value of many immunostimulants is sparse. Looking critically at the immunomodulatory drugs available and making attempts to evaluate the effects of therapy objectively is important. Many agents that have been discarded for use in human medicine are now being resurrected for veterinary use. Is it realistic to expect better results in veterinary patients? This discussion is limited to drugs currently marketed for use as immunomodulators or for which published evidence of activity exists. Advances in genetic engineering have made available recombinant forms of many cytokines with immunomodulatory potential, but only those with some established value are discussed.

1.4.2.1 PHYSIOLOGIC PRODUCTS

1.4.2.1.1 Immunoglobulins

The use of immunoglobulins for treatment of failure of passive transfer of immunity is discussed in Chapter 1.3, and antigen-specific passive immunoglobulin therapy is discussed subsequently. Other forms of immunoglobulin immunomodulation include the use of monoclonal or polyclonal sera directed against components of the immune system. This type of therapy still has not found practical application in the 30 years since the advent of monoclonal antibody technology, largely because of the immunogenicity of the antibodies themselves. Although recombinant technology now has the prospect of resolving this problem, no current examples of clinical applicability in the horse exist.

Another mode of immunoglobulin therapy is polyclonal intravenous immunoglobulin (PIVIG) therapy using pools of immunoglobulin derived form several thousand donors. PIVIG administration was observed serendipitously to be useful for treatment of autoimmunity,[19,20] and mechanisms proposed include idiotype-antiidiotype network regulation,[21] cytokine regulation, specific antibody interactions, Fc receptor blockade, inhibition of activated complement deposition, and long-term selection of immune repertoires.[22] Although the explanation for the mechanisms underlying the effects of PIVIG are fascinating, good examples of therapeutic success also exist in the case of immunothrombocytopenic purpura.[23] However, diseases such as autoimmune diabetes mellitus are resistant to therapy.[24] No publications describe PIVIG therapy in horses, although this treatment remains an intriguing possibility in this species.

1.4.2.1.2 Cytokines

Given the central role of cytokines in immunoregulation (see Chapter 1.1), their potential as immunomodulators is obvious, and a discussion of the possible use of cytokines as therapeutic agents would 54
be extensive although largely hypothetical. Therefore consideration is limited to the two cytokines that have 55
found clinical application in horses to date.

1.4.2.1.2.1

Interferon-α

The clinical application of interferon-α in the horse has been reviewed extensively.[25,26] Interferon-α has antiviral and immunostimulant properties, and oral administration of interferon-α has been shown to reduce inflammatory airway disease[27] in racehorses.[28] The treatment used was low-dose (50 to 150 IU) natural human interferon-α and resulted in decreased bronchoalveolar lavage cell counts and a noninflammatory cytologic profile.[29] Higher doses (450 IU) were less effective, consistent with results in other species.[26] The efficacy of oral therapy probably depends on effects mediated through oropharyngeal lymphoid tissue because the agent is destroyed in the stomach.

1.4.2.1.2.2

Granulocyte Colony-Stimulating Factor

The clinical application of granulocyte colony-stimulating factor in the horse recently has been reviewed extensively.[26] Granulocyte colony-stimulating factor treatment in neonatal foals results in a sustained, dose-dependent increase in neutrophil count and a left shift.[30,31] Treatment increases neutrophil production in the bone marrow and shortens the time to release into the circulation. Neutrophil half-life remains unchanged at 8 hours. In horses, canine recombinant granulocyte colony-stimulating factor (Amgen) has been used to treat sepsis and endotoxemia with some success.[26]

1.4.2.2

BACTERIAL, VIRAL, AND PLANT PRODUCTS

A variety of bacterial and fungal microorganisms or microbial products have been identified that have immunomodulating effects on the immune system. A common feature of many of these products is a nonspecific immunostimulant effect, purportedly caused by macrophage activation and release of cytokines including interferons, interleukin-1, tumor necrosis factor, and interleukin-6. Consequently, mild fever and malaise may be associated with this form of treatment. In the horse, these treatments most commonly are used in cases of respiratory infection or sarcoids. An extensive review of the use of these and other immunostimulants in the horse has been published recently.[26]

1.4.2.2.1

Mycobacterial Products

A wide range of mycobacterial fractions have been identified that have immunomodulating ability.[26] The minimal structure with immunologic (adjuvant) activity is muramyl dipeptide, which is a potent adjuvant.[32] Preparations commercially available for use in horses include BCG (bacille Calmette-Guérin), a modified live human tuberculosis vaccine, and protein-free mycobacterial cell wall extracts (Nomagen, Fort Dodge Laboratories, Inc., Fort Dodge, Iowa; Equimune, Vetrepharm Inc., London, Ontario). Efficacy is claimed for treatment of equine respiratory disease. Adverse reactions have been reported after multiple intravenous treatments in horses, resulting in significant interstitial lung infiltration and progressive pulmonary fibrosis. As a result, caution should be exercised in selecting this treatment modality. In horses the major successful application of these products has been in the intralesional treatment of sarcoids, particularly periocular sarcoids.

1.4.2.2.2 *Propionibacterium acnes (Corynebacterium parvum)*

Propionibacterium acnes is a gram-positive anaerobe marketed for use in horses as a killed preparation under the trade name EqStim (Immunovet, Inc., Tampa, Florida) for treatment of equine respiratory disease. The preparation is recommended for use prophylactically before weaning, transport stress or co-mingling, or for the therapy of chronic infectious respiratory disease. In a blind randomized clinical trial, *P. acnes* treatment resulted in early resolution of spontaneously occurring respiratory disease.[26] In healthy horses, *P. acnes* resulted in increased $CD4^+$ T lymphocyte numbers and lymphokine-activated killer cell activity in peripheral blood and bronchoalveolar lavage fluid, increased nonopsonized phagocytosis in peripheral blood leukocytes, and decreased pulmonary cellularity.[33] Overall, this agent is one of the most popular immunostimulants currently marketed for horses, although an extensive literature to confirm its value still is lacking.

1.4.2.3 CpG DNA

In recent years an extensive literature has developed describing the immunomodulatory effects of certain bacterial DNA motifs.[34] The specific immunostimulatory DNA motifs are called CpG sequences, and appropriate sequences for immunostimulation of domestic species have been identified.[35] Much work has been done examining the efficacy of CpG sequences as vaccine adjuvants,[36] as immunomodulators for hyposensitization (see the following discussion), or cancer therapy.[37] However, the value of CpGs as nonspecific immunostimulants currently is being evaluated in horses as a potential new therapy for the future.

1.4.2.3.1 Acemannan

Acemannan is an extract of the aloe vera plant predominately used for treatment of fibrosarcomata in dogs and cats.[26] Acemannan also can be used as a vaccine adjuvant and has antiviral activity. Anecdotal reports describe efficacy for treatment of equine respiratory disease (intravenous) and sarcoids (intralesional), although both forms of treatment are associated with side effects including syncope, tachycardia, tachypnea, and sweating. Controlled studies of efficacy in the horse are lacking. 55

1.4.2.3.2 *Parapoxvirus ovis* 56

Marketed under the trade name Baypamun (Bayer Animal Health, Research Triangle Park, North Carolina), inactivated *Parapoxvirus ovis* has been used extensively in Europe for prophylaxis and treatment of infectious disease in companion animals (including horses) and pigs. This product will be available shortly in the United States. The immunostimulant properties depend on a component of the viral envelope, an increase in natural killer cell activity, and macrophage activation. Efficacy has been demonstrated against viral and bacterial disease in several species,[26] and some evidence indicates that in horses prophylactic administration before weaning reduces signs of respiratory disease after weaning.[38] Studies of treatment of sarcoid found no evidence of efficacy.[39]

1.4.2.3.3 Echinacea

Extracts of *Echinacea angustifolia* have been reported to be an immunostimulant. One study in horses evaluated the effect of an experimental oral echinacea extract on neutrophil number and phagocytosis and on lymphocyte count.[40] Findings provided limited support for changes in cell count and behavior consistent with immunostimulation, but evidence was limited.

1.4.2.4 CHEMICALLY DEFINED AGENTS

Levamisole is a synthetic anthelmintic used for treating nematode infections and also has been reported to restore impaired host immune defenses.[26] Levamisole appears to have little effect on the normal immune system but may stimulate a subnormal response and suppress hyperactive responses. The effects are dose-related, and low doses are reported to enhance responses, whereas higher doses suppress responses. In cattle, levamisole enhances lymphoproliferative responses in vitro, although in vivo co-administration with a vaccine had no immunostimulant effect.[41] Similarly, levamisole did not prevent corticosteroid-mediated immunosuppression in cattle[42] or enhance postpartum lymphoproliferative responses in pigs.[41] Other than anecdotal reports, no published controlled studies of the value of levamisole in horses are available.

1.4.3 Antigen-Specific Immunomodulation

1.4.3.1 VACCINATION AND ADJUVANTS

Vaccination is a critically important tool in preventing infectious disease in human beings and animals, and passive and active vaccination are used extensively in the horse. Specific equine vaccination strategies are presented elsewhere in this book, and the scientific principles and practice of equine vaccination have been reviewed extensively.[43] Active vaccination implies provocation of an antigen-specific immune response by administration of antigen in a dead, live, or DNA vaccine form. Success of all of these forms of vaccination frequently depends on use of an effective adjuvant, a compound capable of amplifying and directing immune responses.[44] As such, adjuvants are one of the most important forms of immunomodulating agents in use in equine medicine.

Passive vaccination is accomplished by administering preformed antibodies as a plasma transfusion or in a concentrated form, as in commercially available tetanus antitoxin. This strategy can be highly effective in diseases for which no product is available for active vaccination (e.g., *Rhodococcus equi*) or in high-risk situations when time is inadequate for protection to be generated by active vaccination. Generally, passive vaccination should be avoided when possible because of the risk of transmission of infection in serum-derived products. An example of this is the association of acute hepatic necrosis with administration of tetanus antitoxin.[45]

1.4.3.2 HYPOSENSITIZATION

Because horses suffer from a number of hyposensitivity diseases, attempts have been made to perform antigen-specific immunosuppression; for example, for sweet itch and recurrent airway obstruction. The principle of this type of therapy is that the immune response to an allergen can be redirected to reduce hypersensitivity disease.

For example, type 1 hypersensitivity disease may depend on a type 2 T helper cell immune response, and treatments that can change this to a type 1 T helper cell immune response may eliminate or control the hypersensitivity disease by changing the immune response from one dominated by IgE to one dominated by IgG.[46] Typically, hyposensitization treatments use injections of the allergen itself, starting with small doses and gradually increasing the dose over time. This form of treatment depends on correct identification of the allergen against which the hypersensitivity disease is directed. The difficulty in identifying these allergens using available intradermal testing methodologies[47,48] may provide an explanation for the mixed success of hyposensitization treatment in horses.[49] Prospects for hyposensitization therapy may be improved by new techniques to produce large numbers of recombinant allergens.[50,51] These allergens are defined far better than conventionally prepared allergen extracts. In initial experimental studies of recurrent airway obstruction, these allergens were found to be far superior in terms of specificity and sensitivity for detection of allergen-specific IgE. Such developments, together with the development of DNA vaccination strategies incorporating CpG immunomodulation for hyposensitization,[52–54] mean that a good chance exists that new and effective therapies will be developed in the future. 56

57

1.4.4 Conclusion

The properties and efficacy of immunosuppressive agents generally are well documented, as are the effect of antigen-specific immunostimulant adjuvants. Of all the non specific equine immunostimulants described in the literature, only interferon-α and *P. acnes* are supported by well-designed and well-performed studies.[28,29,33] Given the interest in this modality of therapy, this lack of experimental information is regrettable and is evidence of the difficulty in designing studies to establish immunostimulant efficacy, possible lack of efficacy of such products in some instances, and the dire need for additional scientific research.

2 # CHAPTER 2 MECHANISMS OF INFECTIOUS DISEASE

2.1 ## 2.1—Mechanisms of Establishment and Spread of Bacterial and Fungal Infections

Maureen T. Long

2.1.1 ### Normal Flora

Dermal and mucosal surfaces provide a life-preserving protective barrier composed of physical, chemical, and microbial defenses. Normal flora contributes to this protective barrier against pathogens while paradoxically providing a source for potential opportunistic invasion. Commensal bacteria are those that benefit from living on or within a host without mediating harm. For a relationship to be commensal, it must be mutually beneficial, and the interruption of this association results in abnormal host development or overt disease.[1] A pathogen is any disease-producing organism; thus a commensal organism has the potential to be pathogenic. Colonization is infection without disease. Skin, gastrointestinal, respiratory, and urogenital colonization occurs early in life and persists unless disrupted.

2.1.1.1 #### SKIN FLORA

The combination of normal flora and mucosal immunity provides an effective barrier against infectious colonization of nondisrupted skin surfaces. Specific bacteria are stratified by site, and certain bacteria multiple and colonize depending on associated adnexa.[2] Most bacteria and fungi on the surface of the skin are not associated with disease; however, yeast and bacteria within hair follicles are more likely to be related to a disease process.[3] Even though horses inhabit an environment heavily contaminated with fecal flora, normal dermal flora in the horse is surprisingly devoid of members of the Enterobacteriaceae.[4] Normal inhabitants include mixed populations of bacteria of species of *Acinetobacter, Aerococcus, Aeromonas, Bacillus, Corynebacterium, Flavobacterium, Micrococcus, Nocardia*, coagulase-negative *Staphylococcus, Staphylococcus aureus, Streptomyces*, and nonhemolytic *Streptococcus* generae.[2] Certain *Staphylococcus* spp. have been associated with skin disease in the horse and these include *S. aureus, S. intermedius*, and *S. hyicus*, whereas species such as *S. xylosus* and *S. sciuri* more often are associated with normal skin.[5] More than 30 species of fungi can inhabit the skin, and *Alternaria, Aspergillus, Candida, Fusarium, Rhizopus*, and *Trichophyton* spp.[2] commonly are present.

2.1.1.2 #### ORAL, PHARYNGEAL, AND RESPIRATORY FLORA

Oral and pharyngeal mucosal flora is associated with health and disease of the upper and lower respiratory system. The oral and pharyngeal mucosa is populated richly with many bacteria, including obligate aerobes, anaerobes, and facultative anaerobes.[6] Aerobic and facultative anaerobic populations are comprised mainly of *Streptococcus equi*, *Pasteurella* spp., *Escherichia coli*, *Actinomyces* spp., and *Streptococcus* spp. Anaerobes actually predominate in the mouth of the normal horse, and colonization of the oropharynx and mouth consists of members of several bacterial genera. Gram-positive and gram-negative anaerobic species inhabit the pharyngeal tonsillar area, and *Bacteroides fragilis* and *Bacteroides* spp. predominate. *Fusobacterium* spp., 59
Eubacterium spp., *Clostridium* spp., *Veillonella* spp., and *Megasphaera* spp. are also common. These same 60
genera are found consistently in horses with lower respiratory infections, indicating that pharyngeal flora is a

likely source of contamination.[6] Contamination of the trachea of the horse occurs frequently, as evidenced by the fact that transtracheal aspiration yields positive bacterial cultures in approximately 30% of normal adult horses and foals.[7] As with skin flora, normal horses have multiple fungal species inhabiting conjunctival, nasal, and oral mucosae. Stabling increases the frequency of ocular fungi in normal horses.[8]

2.1.1.3 INTESTINAL FLORA

In animal models and chronic human conditions, normal flora is considered important for intestinal maturity and containment of disease. Changes in cecal weight, villus-to-crypt ratio, development of gut immunoglobulin A responses, and volatile fatty acid production are affected by suboptimal cecal colonization in germ-free animals.[9] A relationship between severity of mucosal disease and normal flora also has been demonstrated in models of inflammatory bowel disease of human beings.[10]

Bacteria are present in all parts of the intestinal tract of the horse, and the microbial fauna increases in complexity and density aborally.[11] The stomach of the horse is not a sterile environment. A dense population of gram-positive bacterial rods, primarily composed of *Lactobacillus* spp., colonizes the nonsquamous portion of the equine stomach. Substantial colonization of the duodenum occurs with a large population of proteolytic bacteria, and this colonization increases tenfold in the ileum.[12]

Microbial degradation and fermentation of plant material in the large intestine is an important component of nutrient acquisition in the horse. The consumption of cellulose and starch results in the production of volatile fatty acids.[13] The major cellulolytic bacterial species of the large intestine are similar to those of Bovidae, but the strains in the horse produce different arrays of fermentation products.[14] As in cows, *Ruminococcus flavefaciens* is one of the predominate cellulolytic bacteria of the equine cecum. Overall, gram-negative rods are the most populous bacteria, comprising 50% of flora. Gram-positive rods and cocci each represent around 20% of the bacterial population. Predominant species include members of the Enterobacteriaceae, *Butynvibrio* spp., *Streptococcus* spp., *Bacteroides* spp., *Lactobacillus* spp., *Selenomonas* spp., *Eubacterium* spp., *Propionibacterium* spp., *Staphylococcus* spp., and many unclassified rods and cocci.[15] Yeasts and fungi of the order Mucorales have been identified in the cecum of normal horses and are capable of digesting cellulose and starch.[16]

The latest investigations demonstrate a lack of intestinal pathogens in the flora of normal horses as detected by routine culturing of feces. In the largest study to date, fecal shedding of *Salmonella* in normal horses from farms without evidence of salmonellosis was 0.8% in resident horses.[17] Based on limited investigations, the carriage rates of *Clostridium difficile* in normal horses and foals also appears to be low (<1.5%).[18] Intestinal flora in the horse is an important source for extraintestinal pathogens. In studies examining the carriage rate of *Rhodococcus equi*, all horses cultured carried the bacteria regardless of age.[19,20] Furthermore, if the farm had endemic *R. equi* and respiratory isolates contain the 90-kd plasmid, which has been associated with disease, fecal isolates also contained this plasmid.

2.1.1.4 UROGENITAL FLORA

By far most of the work that characterizes equine normal flora has focused on urogenital flora in an effort to gain understanding of the role of uterine contamination or infection in fetal loss. Although the vaginal and vestibular mucosae of mares are colonized with normal mucosal flora, the uterus is considered sterile.

However, typical culturing techniques result in frequent isolation of what might be considered pathogens, and cytologic examination and bacterial counts are important supplemental tests for detecting true infection. Colony counts less than 10 colony-forming units and lack of inflammatory cells indicate uterine or technical contamination.[21] Many bacteria inhabit the external genitalia of stallions, including those considered to be associated with metritis in mares. The predominant aerobe isolated is coagulase-negative *Staphylococcus* spp., followed by *Corynebacterium* spp., α-hemolytic *Streptococcus* spp., and *Lactobacillus* spp. Pathogens such as β-hemolytic *Streptococcus* spp., *Pseudomonas aeruginosa*, and *Klebsiella* spp. can be found frequently in servicing stallions.[22,23] Pregnancy rates appear to be the same in mares bred to stallions with semen infected with *P. aeruginosa*.[24]

2.1.1.5 FUNGAL FLORA

Essentially the same principles apply regarding normal flora, host immunity, and specific virulence factors for the pathogenesis of fungal infection. Fungal infections can be divided into primary or opportunistic pathogens. True pathogens are less dependent on host status than are opportunistic pathogens, although even a true pathogen may require some degree of alteration of normal flora or host immunity to become established. Long-term antibiotic use, immunosuppression, and compromised organ function especially involving the pulmonary or endocrine system are three primary host factors highly associated with establishment of opportunistic fungal infection. Fungi often can adapt to the mammalian environment over a short time. Adaptation usually requires a change in thermal range, oxygen requirements, and resistance to host defenses. 60

61

2.1.2 Population Biology of Bacterial Infections

Inoculum size, virulence of the organism, and microbial resistance are three important determinants in the outcome of infectious challenge. Understanding the importance of inoculum size in bacterial pathogenesis in general and for a particular bacterium has profound implications for prevention and management of disease. Minimizing the size of bacterial challenge by controlling environmental contamination is the ultimate goal of any management strategy for animals in their natural environment and in hospital settings. Control of environmental challenge dose is especially important in the control of nosocomial and iatrogenic disease.

2.1.2.1 INOCULUM SIZE

Although inoculum size and development of disease are studied frequently in equine viral diseases, comparatively little dose-response work is done to demonstrate a clear relationship between frequency or severity of disease and dose for many equine bacterial pathogens. In general, for systemic infections, inoculum size is the most important determinant of disease in hematogenously disseminated infections such as meningitis and, in rodent models, osteomyelitis.[25,26] Failure of passive transfer, immunodeficiency, infection in multiple joints, and infection with *Salmonella* spp. are important determinants in survival regarding equine neonatal osteomyelitis, but actual data on bacterial characteristics are limited. For skin infections, colonization of experimentally induced wounds with *Staphylococcus* spp. depends on inoculum size.[27] Thus control of surgical and wound hygiene depends on agents to which *Staphylococcus* is sensitive. The occurrence of diarrhea has been demonstrated to be dose-dependent in salmonellosis in calves,[28] but little is known regarding challenge dose in the foal or the adult horse. Minimal inoculum size is required for certain pathogens that form toxins, such as *Escherichia coli* and *Clostridium* spp. For instance, disease in human

beings caused by *E. coli* 0157:H7 requires a small inoculum, and other factors such as diet or antibiotics promote colonization of a few organisms, resulting in severe disease.[29]

2.1.2.2 VIRULENCE

Virulence is the ability of an organism to cause disease.[1] Virulence of an organism frequently is tested by inoculation of different strains of a pathogen into groups of a rodent species and evaluation of lethality or invasiveness. Using this particular methodology, the severity of many diseases frequently is found to be strain-dependent, and virulence commonly is associated with certain phenotypic characteristics of a particular strain. For example, severity of pulmonary disease resulting from *Klebsiella pneumoniae* depends on differences in capsular size and colony morphology.[30] These characteristics become the focus of future investigations and eventually may be defined as virulence factors.

2.1.2.3 ANTIBIOTIC RESISTANCE

Widespread use of antibiotics in animal and human infection occurred following World War II.[31,32] Within 30 years, resistance of gram-positive organisms already was occurring in human pneumococcal infections.[33] From the 1960s to the 1980s, staphylococcal resistance progressed from initial methicillin-resistant organisms to vancomycin-resistant organisms.[32] As a result, for gram-positive and gram-negative organisms, progressive resistance has resulted in less effective means for therapeutic intervention.

Although specific types and mechanisms of bacterial resistance are discussed elsewhere, high-grade and intermediate resistance occur, which are speculated to have arisen from different processes. In terms of bacterial pathogenesis, intermediate resistance occurs in geographically defined isolates in a stepwise fashion resulting from genetic changes under antibiotic pressure. Thus proper dose and length of antibiotic exposure is important in preventing the development of these isolates.[33,34] High-grade resistance is associated with multidrug resistance.[35] In high-grade and multidrug forms of antibiotic resistance, clonal expansion of small numbers of isolates occurs.[35] Individual carrier animals and persons are important for high-grade and multidrug resistance in addition to selective antibiotic pressure. Of note is the fact that commensal or noninvasive pathogens have higher reportage rates for resistance, whereas more highly pathogenic or invasive organisms have less resistance. Thus virulence and antibiotic resistance are not synonymous. Because commensal organisms are ubiquitous, they have a higher likelihood of contact with bacteria that have multiresistance genes. Thus commensal organisms eventually become a reservoir for resistance genes.[36]

2.1.3 Development of Disease and the Role of Normal Flora

2.1.3.1 DISRUPTION OF NORMAL FLORA

As stated earlier, development of disease is caused by disruption of normal flora and invasion by a pathogen or the conversion of a common commensal organism into a pathogen. The pathophysiology of certain types of
equine colitis and pleuropneumonia provide examples consistent with each of these two circumstances. 61
Disruption of normal gastrointestinal flora is likely the underlying pathogenic mechanism for development of 62
acute enterocolitis. Development of colitis in the horse, presumably from disruption of fecal flora, has been associated with feed change, antibiotics, surgery, nonsteroidal antiinflammatory drugs, and transport.[37–39]

Rapid change from a roughage diet to concentrate results in increased numbers of anaerobes, decreased numbers of cellulolytic bacteria, decreased cecal protozoa diversity, and decreased pH in the equine cecum.[37] Isolation of *Clostridium difficile* increases in horses administered antibiotics, and *C. difficile* diarrhea associated with ampicillin, erythromycin, penicillin, and potentiated sulfonamides has been reported in adult horses.[38,40] In ponies infected with *Salmonella* spp., transport and surgery reactivated infection and diarrhea, and antibiotics (oxytetracycline) prolonged shedding.[39] In a case-control study, potentiated sulfonamides were not associated significantly with development of diarrhea in hospitalized horses; however, overall antibiotic use was associated highly with the occurrence of diarrhea.[41]

Several mechanisms exist by which antibiotics disrupt normal gastrointestinal flora and intestinal function. These mechanisms include disruption of carbohydrate metabolism, decreased metabolism of bile acids, direct effects on intestinal motility, and alterations in intestinal mucosa. Change in carbohydrate metabolism is a large intestinal event following decreased microbial reduction of carbohydrates to short-chain fatty acids (SCFA). Because SCFA metabolism and absorption results in fluid and electrolyte absorption, a sudden decrease in SCFAs leads to osmotic diarrhea with intraluminal accumulation of organic acids, cations, and carbohydrates. In human studies, reduced SCFAs have been demonstrated with many antibiotics, including ampicillin, metronidazole, and erythromycin. Bile acids, reduced in the colon by dehydroxylating bacteria, are potent colonic secretogues. Increases in fecal bile acids have been demonstrated in human beings with the use of ampicillin and clindamycin. Erythromycin and amoxicillin directly affect colonic motility.[42] Erythromycin is a motilin receptor agonist that stimulates contraction of antral and duodenal smooth muscles.[43] In the horse, erythromycin results in a dose-dependent increase in ileocecal emptying.[44] Motility-enhancing effects also have been observed in human patients treated with amoxicillin.[42]

2.1.3.2 DISEASE CAUSED BY COLONIZATION OF COMMENSAL FLORA

Occurrence of infectious lower respiratory disease in the adult athlete is an example of the conversion of several commensal bacteria into pathogenic organisms because of contamination of a normally sterile site. Changes in upper respiratory mucosal flora and transportation are two important elements that contribute to the development of pleuropneumonia in horses. The tonsillar mucosa of the oropharynx is colonized heavily with *Streptococcus equi*, and necrosis of this tissue occurring during viral infection is associated with spread to the lower respiratory tract.[6] The association of transport as a risk factor for the development of pleuropneumonia in horses was demonstrated in a retrospective study where transport of greater than 500 miles was associated highly with disease.[45] Elevation of the head for an extended duration is an important initiating event. Natural feeding behavior of horses, which results in a lowered head for several hours, is likely an important method for tracheal clearance. Under experimental conditions, elevation of the head for prolonged periods results in an increase in types and multiplication of oral/pharyngeal commensal bacteria within the trachea.[46,47] *Pasteurella, Actinobacillus*, and *Streptococcus* spp. are the most frequent and prolific colonizers of the trachea after prolonged head elevation. In addition to prolonged head elevation imposed by transport, decreased phagocytosis of equine peripheral neutrophils occurs in horses exposed to extended travel.[47] As a result, common commensal bacteria of the oropharynx and upper airways become opportunistic pathogens.

2.1.3.3 NOSOCOMIAL INFECTIONS

Nosocomial infections are defined by the Centers for Disease Control and Prevention as "an adverse reaction to toxin or infection that was not present or incubating at the time of admission to a hospital."[48] The Centers for Disease Control also have case definitions for each body site and particular infection in human nosocomial disease. No central mechanism exists for detecting and documenting nosocomial infection in veterinary medicine, and frequently many such infections go unrecognized. Nosocomial infections are becoming a major problem for large animal veterinary teaching and private referral hospitals. Infections with *Serratia marcescens, Acinetobacter baumannii, Staphylococcus aureus*, methicillin-resistant *Staphylococcus* spp., *Enterococcus* spp., and various *Salmonella enteritidis* serovars have been reported in association with nosocomial infection in equine patients.[49–59] Surgical incision infection, joint sepsis, catheter phlebitis, wounds, and diarrhea represent the common clinical nosocomial syndromes reported in horses.[49,51–59] When nosocomial infection involves the acquisition of isolates from the hospital environment, these isolates are more difficult to treat because they frequently undergo high-level antibiotic pressure and attain multiresistance. These organisms also have been shown to cross species lines. Reports of nosocomially transmitted salmonellosis in equine hospital wards are increasing, and outbreaks of *S. enteritidis* serotypes 62
Krefeld, Saint Paul, DT104, and Anatum have demonstrated attainment of multiple antibiotic resistance over 63
the course of the outbreak.[50–54] Only one study of a nosocomially transmitted *S. enteritidis* (serotype Heidelberg) did not demonstrate significant acquisition of multiple antibiotic resistance over time.[60]

2.1.4 Pathogenesis of Bacterial Infections

The ability of bacteria to gain entry and cause disease results from a combination of factors possessed by the agent itself, environmental conditions, and status of host defenses. Bacteria gain entry through a body surface by direct inoculation or colonize and damage a dermal or mucosal barrier to cause disease. Environmental or risk factors specific for individual diseases increase the probability of successful penetration or colonization and are discussed for specific diseases in various chapters. Innate and specific immunity, which alter host susceptibility to disease, also are discussed elsewhere in this text. Mechanisms that are specific to bacteria and enhance disease are virulence factors. Virulence factors may allow bacteria an advantage to gain entry and disseminate or may cause damage to the host directly once entry has been gained.

2.1.5 Factors That Enhance Entry of Bacteria

2.1.5.1 ADHESION AND ENTRY

Fibrillar adhesins, nonfibrillar adhesins, and membrane ruffling are virulence factors for bacterial invasion because they aid in colonization of host surfaces. The most common type of adhesin found in gram-positive and gram-negative bacteria are lectins.[61–63] These proteins are highly conserved in bacteria and are important targets for immunoprophylaxis. Although attachment is thought to be the primary role of these proteins, attachment itself results in an intracellular change including actin rearrangements, cell signaling regulation, or actual secretion of bacterial substances into the host cell.

2.1.5.2

FIBRILLAR ADHESINS

Multiple types of fimbria occur in gram-positive and gram-negative bacteria, with gram-negative papillae the most well characterized.[64] Fimbriae are filamentous appendages that are not flagella and do not function in bacterial conjugation.[62,65] Pili or fimbriae are rod-shaped structures composed of an orderly array of a single protein usually arranged helically to form a cylinder. The tip of the fimbria mediates attachment to carbohydrate moieties on cell surfaces and is integral to bacterial invasion and colonization. Bacteria also can contain multiple types of pili. The bacterial pili themselves and the cellular pathways bacteria use for secretion and formation of pili are targets for pharmacologic intervention.[62] Type I fimbria are distributed in the periplasmic space and translocated to the cell surface by a chaperone/usher pathway. These pili are made up of multiple major pilin subunits compiling a rigid shaft with minor pili proteins composing the flexible tip. The chaperone is a special bacterial cell protein that prevents the pilus from achieving its final figuration while in the periplasmic space located between the inner and outer membrane before assuming its position on the outer membrane. *Salmonella* bacteria and uropathogenic *Escherichia coli* commonly possess type I pili. The K88 and K99 fimbriae of enteropathogenic (EPEC) *E. coli* are also type I pili. *Haemophilus* spp. and *Klebsiella* spp. contain type I pili. Type IV pili are located at the pole of the cell and assembled via the type II secretion system that is called the general assembly pathway.[63,65] These pili are flexible fibers of variable length that can aggregate, are important in the formation of microcolonies, and are responsible for the twitching motion of bacteria. The proteins are secreted into the periplasmic space but remain anchored to the inner membrane. The protein then is assembled and passed through a pore formed in the outer membrane. This type of pilus commonly is found on *Pseudomonas aeruginosa*, enterotoxigenic *E. coli*, and EPEC. Curli fimbriae are solid surface structures that use the extracellular nucleation/precipitation pathway.[63] This pilus is secreted as a soluble protein extracellularly with a second protein, the nucleator, for stability.

In gastrointestinal and urinary tract infections, fimbriae are likely one of the most important virulence factors for successful invasion.[64] Although the importance of *E. coli* adhesive fimbriae is questionable in equine disease, they nonetheless provide a model by which these organelles assist bacteria. Once receptor-mediated attachment occurs, intracellular calcium concentration increases in the host cell.[64] Proteins and protein kinases involved in the breakdown of actin are activated, resulting in the disruption of microvilli. A change occurs in the cytoskeleton of the cells and permeability to ions and water. Ions are secreted, resulting in the classic secretory diarrhea. The specificity of the receptor determines the host species susceptibility to the bacteria itself and the ability of the bacteria to colonize a specific body site or surface.

The classic example of pili-mediated attachment is EPEC; however, receptors for EPEC have not been identified in the horse. Enterotoxigenic *E. coli* have been isolated from foals.[66] Although this bacterium is able to cause gastritis and enteritis in experimental infection, adhesion to foal intestinal mucosa was not demonstrated despite the fact that this same organism could adhere and colonize swine epithelium. The antiphagocytic M-protein of *Streptococcus* spp. is actually a fibrillar protein and also assists, but is not essential for, adhesion. In anaerobic bacteria, antibodies to flagellar proteins FliC and FliD can block 63
Clostridium difficile adhesion. These proteins are thought to mediate intestinal adherence and colonization.[67] 64

2.1.5.3

AFIMBRIAL ADHESINS

Afimbrial adhesins are cell proteins that enhance the binding of bacteria to host cells. They also are called "microbial surface components recognizing adhesive matrix molecules."[68–70] Gram-positive organisms

possess afimbrial proteins on their surfaces that presumably aid in binding to host cells. The three most commonly studied afimbrial adhesins are those that bind salivary glycoprotein, bind fibronectin, or are composed of lipoteichoic acid.[70,71] Salivary-binding proteins commonly are found in pathogens and commensals of the oral cavity. *Streptococcus* spp. and *Actinomyces* spp. possess these proteins. Fibronectin-binding protein (FBP) is necessary for *Staphylococcus aureus* invasion and binds fibronectin and collagen to form a bridge between the FBP and the host cell integrin (fibronectin integrin $\alpha_5\beta_1$).[72,73] FBPs are essential for invasion of epithelial and endothelial cells as demonstrated by the fact that *Streptococcus pyogenes* FBP mutants do not bind to epithelial cells in vitro.[68–70] Heterologues of FBP have been demonstrated in *S. pneumoniae* of human beings, *S. equi equi*, and *S. equi zooepidemicus*. Other potential equine pathogens that have FDPs on their surface include *Actinomyces* spp., *Enterococcus faecalis*, and *Listeria monocytogenes*.[71,74] Lipoteichoic acid is a common binding factor found in *Streptococcus* group A bacteria, and antibodies to this protein inhibit adhesion of the bacteria to cells.[75] This protein is also important in stimulation of cytokine secretion from the cells during infection, and lipoteichoic acid has been demonstrated in group B *Streptococcus*, including *S. equi equi*.[76] A less commonly described afibrillar adhesin is composed of surface polypeptide chains in *Corynebacterium* that bind to lectin.[77] Binding of these proteins can be abolished by trypsin treatment. Afibrillar adhesins are also present in gram-negative organisms, the most commonly studied are conserved high-molecular-weight adhesion proteins of *Haemophilus influenzae* and *Bordetella pertussis*.[75]

2.1.5.4 CYTOSKELETAL CHANGES

Binding of bacteria frequently results in cytoskeletal changes within the host cell to enhance susceptibility to invasion. Membrane ruffling is a virulence factor that results in internalization or breakdown of intracellular components to allow for invasion of tissues. The two models of membrane transformation commonly are referred to as zipperlike or triggerlike, and bacteria commonly studied in this phenomenon include *Yersinia* spp., *Listeria monocytogenes*, *Salmonella* spp., and *Shigella flexneri*. Binding results in actin rearrangement and engulfment of these intracellular bacteria by phagocytic and nonphagocytic cells. *Yersinia* and *Listeria* form a zipperlike relationship in which the tightly adhered bacteria result in actin polymerization and formation of a phagocytic cup.[78] This three-stage process is controlled by different proteins, the first of which initiates actin nucleation and branching of filaments. A second protein stimulates actin polymerization and depolymerization, which is followed by activation of a third protein that ends the process. *Salmonella* and *Shigella* bacteria adhere and secrete proteins that are translocated into the host cell cytoplasm and trigger actin polymerization. Bacterial proteins are secreted into the cell,[79] and an actin-binding protein forms a complex with the cell protein, T-plastin. In the presence of F-actin, an increase in actin bundling of T-plastin occurs primarily in the vicinity of bacterial-host cell contact, resulting in enhanced *Salmonella* invasion. In addition to membrane ruffling, *Mycobacterium avium* and *Salmonella* spp. rely on activation of intracellular guanosine triphosphatases leading to phagocytosis.[80,81]

2.1.6 Factors That Enhance Spread of Bacteria

Once colonization occurs, multiplication and spread of bacteria is enhanced through virulence factors. These factors assist bacteria in evasion of immune defenses, use of the host environment, and breakdown of tissue barriers. Many of these defenses overlap, but the end result is avoidance of destruction by the host and sublimation of host tissues into a new bacterial niche.

2.1.6.1 EVASION OF IMMUNE DEFENSES

2.1.6.1.1 Capsule

One of the most common and potent strategies for avoidance of phagocytosis is the presence of a capsule. The polysaccharide components of capsule are important targets for control of bacterial infections. Immunization strategies against capsular components, such as with vaccination against *Haemophilus influenzae* infection in human beings,[82,83] has been successful in the control or elimination of this disease.

Bacteria are diverse and many have a capsule, but assembly and structure of the capsule is remarkably similar between bacteria. The *Escherichia coli* capsule is representative of the majority of gram-negative capsule types.[84] Three genetic regions control the development of capsule, and all are targets for intervention. The first region controls transport and assembly of the mature polysaccharide through the outer membrane. The second genetically encoded region controls formation and polymerization of 64
polysaccharide itself. The complexity of the resulting protein product depends on the size of this region. 65
The third genetic locus contains genes that are involved in translocation of the polysaccharide through the inner membrane.

The capsule of bacteria is composed mainly of polysaccharide, which is inherently a poor immunogen. Ultrastucturally, the capsule in *E. coli* and *Klebsiella pneumoniae* is a fine fibrillar meshwork covering the bacteria surface; however, the capsule of *Klebsiella* is approximately 20 times thicker than that of *E. coli*.[85] In Enterobacteriaceae, the K antigen is one of the major antigens of this complex and expression is temperature dependent.[86] The presence of certain K antigens and a large capsule, as studied in *Klebsiella* virulence, is associated highly with increased pathogenicity and resistance to phagocytosis.[87,88] The other major antigen is the lipopolysaccharide without the lipid A component of the molecule. A third minor component, colanic acid, appears to exhibit antiphagocytic activity in some *E. coli*. Classically, the presence of capsules on *E. coli* have been shown to prevent complement-mediated phagocytosis.[89] Lipopolysaccharide itself activates complement, and the capsule prevents immune activation by concealing the lipopolysaccharide molecule. Introduction of the genes associated with production of a more viscous capsule into a bacteria change an avirulent phenotype into a virulent phenotype.[90]

As early as 1928 the engulfment and digestion of *Streptococcus pneumoniae* was observed to be associated with lack of capsule.[91] By 1940 this virulence factor was understood to be genetically encoded.[92] Early studies with *S. equi equi* demonstrated that resistance to phagocytosis was associated with an increase in capsule and M protein,[93] and in a model of *S. equi zooepidemicus* infection in mice, enhancement of virulence was associated with increased capsule and resistance to phagocytosis.[94] Although colonization of the guttural pouch occurs with nonencapsulated *S. equi equi* strains, induction of lymphadenopathy is correlated more to the capsular strains. Recent studies have shown that when M protein content is kept constant, the amount of capsule actually is correlated with resistance to phagocytosis.[95] Resistance to in vitro phagocytosis can be abolished with treatment with hyaluronidase. In support of this, phagocytosis of *S. equi equi* and *S. equi zooepidemicus* can be enhanced significantly in a murine model by induction of specific immunity against the hyaluronan component of this capsule.[96]

The two most important underlying components of abscess formation are (1) resistance to phagocytosis and (2) failure of bacterial clearance. Capsules of anaerobic bacteria are unique, and their role in virulence may account directly for the formation of abscesses within the host. The capsule of *Bacteroides fragilis* has two distinct polysaccharides composed of repeating subunits with oppositely charged groups (zwitterion).[97] This polysaccharide complex injected alone promotes the induction of abscess. Development of antibody against these polysaccharides prevents abscess formation.

Infection of rodents with the encapsulated form of *Bacteroides* spp. and *Fusobacterium* spp. results in the formation of intraperitoneal abscesses, whereas nonencapsulated bacteria do not cause abscessation.[98–100] Higher mortality is associated with encapsulation in these models. Synergism of capsular anaerobes with other bacteria occurs; nonencapsulated bacteria have enhanced survival in abscesses and produce capsules when cultured or inoculated with encapsulated bacteria.[99]

2.1.6.1.2 Anticomplement Factors

Similar and overlapping with the function of capsules are structural proteins that block complement. The O side chain of lipopolysaccharide on gram-negative bacteria is an anticomplement factor.[101] The longer the side chain, the farther the distance between phagocytes and the bacteria. Many capsules contain sialic acid, the interaction of which with O antigen prevents the formation of C3 convertase.[102] Bacterial enzymes are formed by *Streptococcus* spp. and other organisms that damage the polymorphonuclear cell chemoattractant C5a.[103–106] Production of a protein in *Salmonella* spp., encoded by the *rck* gene, prevents insertion of the C9 fragment of complement into the bacterial membrane.[9]

The M proteins of *Streptococcus* spp. are considered important for resistance to phagocytosis. Specifically, for *S. equi equi*, the M protein appears to decrease deposition of complement on the surface of the bacteria. The hypervariable region of the M protein of *S. pyogenes* and *S. pneumoniae*[107,108] confers this resistance to phagocytosis.[109] The M protein of *S. equi zooepidemicus* is 90% homologous in the hypervariable region and likely mediates the same function.[93] This mechanism for complement resistance appears to be through enhancement of binding of fibrinogen to the bacteria in the presence of M protein.[110–112] When fibrinogen is present on the outer surface of the bacteria, phagocytosis is blocked.

2.1.6.1.3 Phagolysosomal Survival

The intracellular environment should be inhospitable for bacteria, yet many organisms are ingested by phagocytic cells and use the intracellular environment to multiply and disseminate. In normal phagolysosomal fusion the phagocytic vesicle first becomes fused with a host cell endosome. Shortly thereafter, fusion with the lysosome occurs. Several digestive proteins are released within the lysosome and a drop in pH occurs, resulting in inactivation and digestion of a foreign protein or microorganism. *Shigella* 65
spp. and *Listeria monocytogenes* are bacteria that escape the phagocytic vesicle to multiply in the host cell 66
cytoplasm.[113]

Extended survival (and replication) in the phagosome itself is an important strategy for dissemination of bacteria. The two main mechanisms for phagosome survival include (1) inhibition of phagolysosomal fusion and (2) blockage of the formation of lysosomal enzymes once phagocytosis occurs. Before escape from the phagosome, *Listeria* modulates maturation of the phagosome by delaying fusion with the

lysosome.[114] One of the earliest observations of *Mycobacterium tuberculosis* infection in cell culture was uninhibited multiplication within macrophages.[115] Later studies determined that *Mycobacterium* and *Legionella* cause a change in the maturation of the phagosome.[116] Once the phagosome is infected, many lysosomal proteins appear in it, yet others do not, indicating a manipulation of the environment after fusion. Engulfment of *Salmonella* in the phagosome appears to induce formation of an actual phagolysosome, but the organism survives nonetheless.[117] Acidification occurs, but production of reactive oxygen species is decreased. In addition, *Salmonella* appears resistant to reactive oxygen, which is controlled by a number of *oxy* genes that are upregulated in response to oxygen stress. This occurs rapidly, within 20 minutes of intracellular uptake of the bacteria.[118] Many bacteria that are resistant to reactive oxygen are able to make catalase and superoxide dismutase.

Inhibition of phagolysosomal fusion itself is an important protective mechanism of bacteria. *Rickettsia*, *Neorickettsia* (formerly *Ehrlichia*), and *Rhodococcus* spp. bacteria appear to inhibit phagolysosomal fusion. More detail regarding mechanism of this phenomenon is given in the section on equine *Ehrlichia. Rhodococcus equi* also inhibits phagolysosomal fusion, and although the mechanism of inhibition is unknown, opsonization by *R. equi*–specific antibody results in enhanced fusion and killing.[119,120] Resistance to phagolysosomal fusion appears to depend on the presence of the 90-kd virulence plasmid.[121]

2.1.6.2 ADAPTATION TO HOST ENVIRONMENT

2.1.6.2.1 pH Resistance

The acid tolerance response is important primarily for intracellular bacteria as a way to survive the acidification within a mature phagolysosome. Many bacteria including *Listeria monocytogenes, R. equi*, and *Salmonella* spp. are able to withstand highly acidic environments.[120,121] Genes that control virulence in *Salmonella* actually are upregulated by an acidic environment.

2.1.6.2.2 Bacterial Nutrition

Nutrition of bacteria is associated intimately with cellular and tissue environments. Although bacteria use iron for many enzyme systems, the relationship between bacteria and iron is more complex. The proper level of iron is important because iron is required for the production of reactive oxygen intermediates. The *fur* gene in *Escherichia coli* was identified first as the major regulator of iron acquisition.[122] Homologues of this gene have been identified in many other bacteria, including *Salmonella* spp., *Vibrio* spp., *Pseudomonas aeruginosa*, *Staphylococcus aureus*, and *Bacteroides fragilis*.[122–127] This gene regulates the amount of iron handled by the bacterial cell depending on the host stores. In times of iron stress, the gene is downregulated to allow for more iron uptake from the environment by the bacterial cell. In addition, bacteria possess siderophores, which are potent chelators of iron.[128] These siderophores are secreted outside of the bacterial cell, where they take up iron, and are taken back into the cells through a receptor-mediated process. After internalization, iron is cleaved and used by the bacteria. Resistance to carbon and nitrogen starvation are two other means assisting bacterial survival in inhospitable environments.

2.1.6.3 DAMAGE TO HOST TISSUES

2.1.6.3.1 Toxins

Exotoxins are virulence factors secreted by bacteria generally to aid spread of infection. Gram-positive and gram-negative organisms secrete an array of exotoxins. Classically, three types of exotoxins occur[129]: (1) the A-B form with two distinct parts for binding and for enzymatic action, (2) toxins that form pores within host membranes, and (3) superantigens that form a bond between the major histocompatibility complex class II receptor of macrophages, resulting in release of various T helper cell–mediated cytokine cascades. Several examples of common equine pathogens follow.

Toxins of *Staphylococcus aureus* are well characterized and are associated directly with the pathogenesis of disease.[130] Toxins that may be important for disease in the horse include the four hemolysins, toxic shock syndrome toxin 1 (TSST-1), exfoliative toxins, and leukocidin. Few overt syndromes are recognized in the horse that are caused specifically by *S. aureus*. However, *S. aureus* is the most common bacteria isolated from cellulitis and joint infections in adult horses. Cellulitis induced by *S. aureus* in the horse may be similar to wound-associated toxic shock in human beings. Toxic shock syndrome is a disease of increased capillary permeability characterized by hypotension, hypoalbuminemia, and edema. The toxins of *S. aureus* work in concert to (1) induce massive release of cytokines, (2) increase sensitivity to cytokines, and (3) damage endothelial cells directly. The superantigen toxin of *S. aureus* forms a bridge between the major histocompatibility complex receptor on macrophages and the T cell receptor resulting in a massive release 66
of interleukin-2 (IL-2). The downstream effect is T cell proliferation and induction of type 1 cytokines that 67
stimulate release of proinflammatory cytokines from macrophages. Exfoliative toxin also induces T cell proliferation. TSST-1 and exfoliative toxin of *S. aureus* enhance the effects of endotoxin in cell culture and live animal experiments. In rabbits the lethal dose of endotoxin is decreased by 100-fold. The TSST-1 binds directly to endothelial cells and in endothelial cell culture demonstrates cytotoxicity. A dose-dependent induction of leakage across monolayers also occurs. Exfoliative toxin and TSST-1 have been identified in equine *S. aureus* isolates associated with severe phlegmon and metritis.[131,132]

Alpha-toxin has been studied intensely and is directly toxic to many cell types.[129] This toxin can damage erythrocytes, skin, and nerve cells and is lethal.[130] At high concentrations, molecules of the toxin polymerize and form pores in monolayers of cells resulting in permeability of the cells. The arachadonic acid cascade is activated, resulting in thromboxane- and prostacyclin-mediated vasoconstriction in the face of edema formation. Alpha-toxin also appears to act directly on platelets, resulting in release of procoagulant factors. Increased permeability and swelling of cells may be important in the pathogenesis of dermal and neural damage. Myelin sheath destruction is the lesion observed in rabbits. The toxin, β-hemolysin or sphingomyelinase C, is produced in high concentrations in many *S. aureus* isolates, and the degree of pathogenicity to erythrocytes likely is determined by sphingomyelin content of erythrocytes of different strains and species. This toxin has high amounts of phosphorylase C activity in the presence of Mg^{2+}. The presence of this toxin appears to be correlated with enhanced growth characteristics. The toxins γ-hemolysin and leukocidin appear to cause degranulation of leukocytes, with leukocidin being the more potent of the two. Finally δ-toxin is toxic to erythrocytes and cellular organisms and also is lethal at high doses.

2.1.6.3.2

Clostridial Infections

Clostridrium spp. mediate clinical disease by producing exotoxins. The clostridial bacteria causing botulism and tetanus excrete neurotoxins to which horses are highly susceptible. The main toxins of botulism and tetanus are remarkably similar even though they exert effects that appear to be opposites, with botulism causing a flaccid paralysis and tetanus causing a spastic paralysis.[133] Both toxins share amino acid sequences of metalloproteinases that are most similar to zinc-requiring endopeptidases. With botulism, at least six serologically different neurotoxins occur, with most reports in horses caused by type B toxin, although A, C, and D also have been identified.[133–137] Only one tetanus neurotoxin is responsible for the clinical signs of spastic paralysis.

Neurotoxin is secreted as a progenitor and must be cleaved by proteases (trypsin) to the derivative toxin to produce clinical signs. The active toxin consists of a light and heavy chain (A-B type toxin) that mediates paralysis by blocking acetylcholinesterase in a three-step process.[129,138] The first step is rapid and involves recognition and binding of the neurotoxin to its receptor on the nerve. In the second step, translocation occurs as the active site of the molecule is internalized in the nerve cell ending by endocytosis. The acidified vesicle induces a conformational change in the toxin so that it can be translocated to the cytosol. The third and final step is the slow step in which cell neuroproteins called synaptopeptidases are cleaved, preventing acetylcholine release. The proteins that are cleaved by the neurotoxin include synaptobrevin, synaptosome-associated membrane proteins, and syntaxin. The protein synaptobrevin is a component of the neurotransmitter cell membrane, is essential for neurotransmitter release, and is involved in exocytosis of the neurotransmitter vesicle and axonal growth. Syntaxin is important for vesicle and cell membrane fusion. The inactivation of one or more of these proteins accounts for the prevention of release of synaptic vesicles. The different botulinum neurotoxins exhibit variable specificity to these proteins. Types B, D, F, and G are active against synaptosome-associated membrane proteins, whereas A, C, and E are active against synaptobrevin, and C is the only form that cleaves syntaxin.

The difference in clinical signs noted between *C. tetani* and *C. botulinum* is a reflection of the binding and level of activity of the respective toxin. *C. botulinum* binds to peripheral nerves, and *C. tetani* binds to cells within the central nervous system. Furthermore, *C. botulinum* toxin binding results in prevention of downstream release of other neurotransmitters, such as γ-aminobutyric acid. Injection of *C. tetani* toxin intravenously in low doses results in flaccid paralysis.

The main pathologic features of disease cause by *C. perfringens* are edema, necrosis, and death, regardless of the site of action.[138] Toxins elaborated by these clostridia include lethal and nonlethal toxins that cause necrosis and hemolysis and frequently contain lecithinases and lipases. *C. perfringens* has four major lethal toxins, an enterotoxin, and three minor toxins. Recent genetic evaluation of equine isolates associated with diarrhea indicate the majority of isolates are type A, the toxic affects of which are mediated by α-toxin.[139] The *cpe*-toxin or enterotoxin has been detected by enzyme-linked immunosorbent assay in 16% to 19% of equine isolates, so disease has been linked to enterotoxigenic type A and nonenterotoxigenic type A strains.[18,140] Individual case reports exist of neonatal diarrhea associated with type B (β- and ε-toxins), type C (β-toxin), and type D (ε-toxin) strains, which also carry the α-toxin.[141,142] 67

68

Classic experiments demonstrate that injection of purified α-toxin into mice results in hemolysis and death, and recent evidence confirms the role of α-toxin as the major virulence factor of gas gangrene.[138] α-Toxin is one of several zinc metalloproteinase enzymes of bacteria including that of *Listeria monocytogenes,*

Bacillus cereus, and other *Clostridium* spp. One enzyme is phospholipase C, which is able to hydrolyze phosphatidylcholine (lecithin) and sphingomyelin.[143,144] This toxin is responsible for cardiovascular collapse and death, likely by increasing vascular permeability. At the cellular level, this toxin can cause platelet aggregation and hemolysis and is cytotoxic and myotoxic. Vascular activity is mediated by upregulation of adhesion molecules in leukocytes and endothelial cells. Endothelial cells and macrophages produce platelet-activating factor in response to toxin exposure. Muscle fibers are damaged by the formation of intravascular aggregates within the muscle.[143]

Recent work with β-toxin and ε-toxin indicates that these toxins act as pore formers.[145,146] Early research into the mechanism of action of β-toxin indicated a role for catecholamine release because of the sudden increase in heart rate and drop in blood pressure when the toxin was injected into experimental subjects.[138] β-Toxin polymerizes and forms pores that act as selective ion channels, the generation of which within cell membranes effectively creates a neurotoxin.[145] Work with ε-toxin indicates that this toxin is able to form large pores within membranes, resulting in a flux of potassium outward and chloride and sodium inward. Later ion flux is dominated by movement of calcium into the cell.[146] This flux results in irreversible morphologic changes in the cell membrane and death of the cell.

Enterotoxin binds directly on the cell membrane, causing a change in ion movements that affects cellular metabolism.[138] Similar to the actions of these other toxins, most of the damage is mediated by increased calcium levels within the cell, affecting cell membrane function and permeability. The newly recognized β_2-toxin has been associated with intestinal disorders in horses; however, the exact mechanisms of action of this toxin are unknown.[147]

C. difficile has five toxins, of which toxins A and B are thought to be most important in development of disease.[148,149] The evidence to date indicates that toxins A and B mediate the pathogenesis of *C. difficile* diarrhea.[149] Research suggests that the formation of the classic pathologic lesion, the pseudomembrane, results from the combined actions of toxin A, toxin B, and IL-8. Classically, toxin A is considered an enterotoxin and lethal, whereas toxin B is a virulent cytotoxin. Toxin A appears to be the primary mediator of fluid accumulation.[150,151] The toxin is thought to bind to an oligosaccharide receptor and is internalized immediately. After a lysosomally mediated acidification step, a rapid fall in intracellular adenosine triphosphate concentration occurs, followed by release of mitochondrial cytochrome *c* and generation of reactive oxygen intermediates. Injection of toxin A results in fluid accumulation, cell necrosis, and recruitment of inflammatory cells. One mechanism of fluid accumulation appears to be by interruption of actin filaments and destruction of tight junctions. Toxin A also results in neutrophil recruitment possibly mediated by the direct action of the toxin on macrophages to stimulate release of IL-1, tumor necrosis factor α, and leukotrienes. In cell culture, toxin A can cause IL-8 secretion (a potent recruiter of neutrophils), cell detachment, and apoptosis of separated cells. Direct activation of macrophages and secretion of IL-8 is through a calcium and calmodulin–dependent mechanism that results in direct nuclear upregulation after nuclear translocation of transcription factors NF-κβ and AP-1.[150] Toxin B is more cytotoxic than toxin A, especially to human epithelial cells.

2.1.6.3.3 Cell Death

Apoptosis is a distinctive morphologic process that results in cleavage of nuclear material and scavenging of unwarranted cells without immune activation.[152] Apoptosis or programmed cell death is an important

pathway for complex organisms to deal with damaged and diseased tissue. Apoptosis avoids the release of the tissue damaging enzymes and nonspecific elimination of tissue that occurs in cellular necrosis. Several bacteria modulate the host apoptotic pathways to enhance survival.[153] *Shigella flexneri, Salmonella typhimurium*, and toxins of *Staphylococcus aureus, Pseudomonas* spp., and *Corynebacterium diphtheriae* have demonstrated programmed cell death as a consequence of cellular infection or exposure.[152,154] A protein of *Shigella flexneri*, IpaB, induces apoptosis by binding to and activating the cellular enzyme caspace 1, which induces apoptosis of macrophages.[113] *Staphylococcus aureus* α-toxin, presumably escapes the macrophage after engulfment and induces host cell apoptosis.[130] The TSST of *S. aureus* induces B cell apoptosis and blocks immunoglobulin production.

2.1.7 Pathogenesis of Fungal Infections

Of the 250,000 species of fungi, fewer than two hundred are true pathogens.[155] Superficial mycoses affect the hair shaft and the superficial epidermis. Cutaneous mycoses (dermatophytosis) infect the epidermis, dermis, hair, and nails of animals, and *Microsporum, Trichophyton*, and *Epidermophyton* are the most commonly associated pathogenic genera. Subcutaneous tissues can become infected with *Sporothrix, Conidiobolus, Basidiobolus*, and 68
69 members of the Dematiaceae fungi, which cause the chromoblastomycosis, mycetoma, and phaeohyphomycosis infections. Most of these infections are introduced by penetration through skin or opportunistic invaders of damaged skin surfaces. *Histoplasma capsulatum, Coccidioides immitis, Blastomyces dermatitidis*, and *Paracoccidioides brasiliensis* are the four most important systemic fungal pathogens. The most common opportunistic infections include *Candida albicans, Aspergillus* spp., *Cryptococcus neoformans, Mucor* spp., and *Pneumocystis carinii*.

2.1.8 Factors That Enhance Entry of Fungi

Fungal virulence factors may be more complex than those of bacteria because of the higher degree of opportunism that occurs primarily because of a change in host status. Subtle factors may combine with host status to result in a certain fungus attaining a virulent state. For example, the typical fungal wall is composed of three major polysaccharides: mannose, glucans, and chitin. Chitin mutants of *Candida albicans* are less virulent when tested in rodent models than wild-type fungi.[156] A mutant *C. albicans* that cannot synthesize complex mannose oligosaccharides does not adhere to other yeast and epithelial cells and has lost virulence in a guinea pig model.[157] Both of these mutants can proliferate in vitro normally, and whether this is an actual virulence factor is unclear.

As in bacteria, adherence is an important characteristic for infection and colonization of the host. Adhesins have been identified in *C. albicans* and *B. dermatitidis*. Two genes have been associated with adhesion in *C. albicans*. The first is a glycoprotein that has sequences consistent with agglutinating activity. Transformation of this gene into other nonadherent fungal species results in adhesion of the transformed yeast to cells.[158] *C. albicans* also has integrin-like proteins, the disruption of which results in diminished hyphal growth, adhesion to cells, and loss of virulence in mice.[159,160] The *B. dermatitidis* adhesin mediates binding to human monocyte-macrophages through the CD14 receptor.[161]

2.1.9 Factors That Enhance Spread of Fungi

2.1.9.1 EVASION OF IMMUNE DEFENSES

Many fungi have polysaccharide capsules that help them resist phagocytosis and immune activation. The capsule of *Cryptococcus neoformans* inhibits leukocyte accumulation, cytokine secretion, and macrophage phagocytosis.[162] Mutants without capsules are highly infective and avirulent. As indicated earlier, many fungi are engulfed by macrophages, and intracellular survival is mediated by virulence factors. Macrophages are capable predators of *Candida albicans*,[163] *H. capsulatum*,[164] and *B. dematitidis. H. capsulatum* is primarily a yeast in vivo, and this form infects macrophages. Phagolysosomal fusion occurs at a normal rate,[165] but blockage of acidification of the phagolysosome occurs.[166]

2.1.9.2 ADAPTATION TO HOST ENVIRONMENT

2.1.9.2.1 Morphology and Temperature

Adaptability to the host environment is also a trait that enhances fungal virulence. Fungal dimorphism, which is the ability to adopt another morphologic state, clearly is tied to virulence. Mutants of *C. albicans* that cannot switch to the hyphal form are avirulent in certain in vivo models, although both forms likely contribute to pathogenesis.[167] In a second adaptation, phenotypic switching, colonies of fungi change during in vitro growth. *Candida albicans*, *Cryptococcus neoformans*, and *H. capsulatum* display phenotypic switching, and different phenotypes are associated with degrees of virulence.[168–171] *H. capsulatum* spontaneously gives rise to mutants that have less capsule, are less virulent, and are not cytotoxic to macrophages.[170] The signal for dimorphic fungi to change form is usually temperature. Many fungal species germinate within the host with increased temperature, allowing for dissemination within the host. Calcineurin is found in many yeast and mammalian cells and in *C. neoformans*. This protein mediates the ability of the fungus to grow at 37°C.[172] Temperature and heat shock also are mediated by the calcium-dependent protein cyclophilin B in *Aspergillus*.[173] Adaptation to mammalian pH is controlled genetically in *Candida albicans*. Mutants display abnormal cell morphology at physiologic pH ranges.[174]

2.1.9.2.2 Nutrients

Nutrient requirements that affect virulence include melanin, iron, and calcium. Melanins are present in the wall of *Cryptococcus neoformans*, and melanin can scavenge reactive oxygen intermediates, making the organism resistant to the oxidative burst of neutrophils.[175] Pathogenic fungi have siderophores and high-affinity ferric iron reductase to acquire iron from low-iron environments.[176,177] *H. capsulatum* secretes a calcium-binding protein that enhances calcium uptake from calcium-poor environments.[178,179] Without this protein, *H. capsulatum* cannot form colonies and does not survive in cultured macrophages.

2.1.10 Damage to Host Tissues

2.1.10.1 TOXINS

Exposure to pathogenic and saprophytic fungi is an everyday occurrence. Respiratory contamination and 69
infection is important for many species, but skin penetration and dissemination from necrotic gut are important 70
portals for large animals also. After initial infection, dissemination depends on previous damage to host tissues, deeper mechanical penetration, or actual invasion of new tissues. *Candida albicans* can grow through and replace cell membranes.[163] True molds invade blood vessels and grow along the intima of the vessels. Fungi secrete many degradative enzymes, including proteinases, phosphatases, and DNAses to surmount structural barriers.[180] Aspartyl proteinase genes allow more persistent colonization of host surfaces and deeper penetration.[181]

When *Coccidioides immitis* invades the host, the fungi form endospores. Endospores secrete proteinase and urease, which likely aid in the breakdown of pulmonary tissues.[182–184] The two proteinases of *Aspergillus fumigatus* break down elastin, a major component of lung tissue.[185,186] Phospholipase activity has been demonstrated in *Candida albicans, Cryptococcus neoformans*, and *A. fumigatus*.[187] Strains of *Candida* spp. with high amounts of this enzyme have enhanced virulence,[188] and abolishing this activity results in decreased adherence of the organism.[189] Host eicosanoids enhance fungal colonization. Recent evidence demonstrates production of eicosanoids by dermatophytes and systemic fungi.[190]

2.1.10.2 APOPTOSIS

Fungi induce apoptosis by a direct effect of a fungal toxin or following host cell cytoskeleton rearrangements.[191] The gliotoxin of *A. fumigatus* can induce DNA fragmentation and apoptosis in macrophages.[192] This toxin also has many other immunosuppressive qualities, including inhibition of the neutrophil respiratory burst and T cell activation.

2.2

2.2—Mechanisms of Establishment and Spread of Viral Infections

J. Lindsay Oaks

Viral infections are responsible for some of the most medically and economically important diseases of horses. A few notable examples include influenza, equine rhinopneumonitis and abortion (Herpesviridae), African horse sickness (Reoviridae), equine infectious anemia (Retroviridae), various encephalitis viruses (Alphaviridae), and most recently in the United States the West Nile virus (Flaviviridae). Specific therapy of viral infections remains a significant challenge because antiviral drugs are generally ineffective, impractical, or cost-prohibitive for the treatment of horses. Treatment of most viral infections focuses on supportive care of the affected organ system(s) and control of secondary complications such as bacterial infection. Currently, control of most clinically significant viral diseases in horse populations relies on vaccination, quarantine, or even destruction of infected animals. 74 75

Despite the great significance of some viral infections, recognizing that many equine viruses are ubiquitous, weakly pathogenic, or not associated with any known disease under normal circumstances is also important. Some examples include equine adenovirus,[1] respiratory and enteric reoviruses[2] (the term *reo* is derived from the acronym for *r*espiratory *e*nteric *o*rphan, indicating that these isolates have not been associated with disease), and equine herpesvirus (EHV) types 2 and 5.[3] Some host-virus relationships may be mutualistic in that virally derived genetic elements are theorized to benefit the host by facilitating genetic variability and evolution.[4] Thus many viruses are of no practical clinical significance, and no control efforts are warranted. For this reason, one should never assume that the recovery of a virus from a clinical specimen indicates significance without proof that the virus can cause the disease in question.

Veterinary virology is a rapidly changing field. New diseases continue to emerge or be discovered; a dramatic example is the Hendra paramyxovirus that appeared in Australia in 1994, killing horses and human beings.[5] More recently, another paramyxovirus, the Salem virus, has been identified in the United States, although the clinical importance of this virus is unclear.[6] Less dramatic but of more relevance to most equine veterinarians is the association of bovine papillomavirus with sarcoids.[7,8] A number of equine diseases occur in which viral involvement has yet to be excluded, including Theiler's hepatitis[9] and lymphosarcoma.[10] Viral origins also likely will be discovered for diseases in which viruses were not suspected previously to play a role; in human beings and mice, viruses have been proposed to have a role in everything from diabetes to obesity.[11,12] However, the greatest advances in veterinary virology are in understanding the molecular biology of viral replication, virus-cell interactions, and virus-host interactions. Related advances in molecular biology techniques, such as the polymerase chain reaction and immunohistochemistry, also are providing sensitive, specific, and rapid tools for the diagnosis of viral infections. In the realm of antiviral drugs, aggressive searches are ongoing for effective and economical drugs for treatment of human beings, and in the near future, antiviral drugs likely will be a realistic therapeutic option for equine veterinarians.[13,14] Finally, significant advances in the design of vaccines likely will improve the efficacy of immunization.

This chapter outlines the general ways that viruses cause disease and describes the most important virus-cell and virus-host interactions that result in pathologic conditions. Although the focus is on equine viruses where possible, the principles described are generally not species dependent, and no attempt is made to limit the discussion to recognized equine viral pathogens or diseases. Discussion of a particular mechanism or virus also should not be taken to suggest that this mechanism or type of virus has been documented in horses. Where possible, supporting references have been selected to include review articles or texts for additional information about key concepts.

2.2.1 Viruses and Virus-Cell Interactions

An in-depth discussion of viral structure, taxonomy, and replication is beyond the scope of this chapter, and the reader is referred to textbooks of veterinary or human virology for more detailed information.[15,16] However, a brief overview is presented to emphasize those features that have clinical relevance.

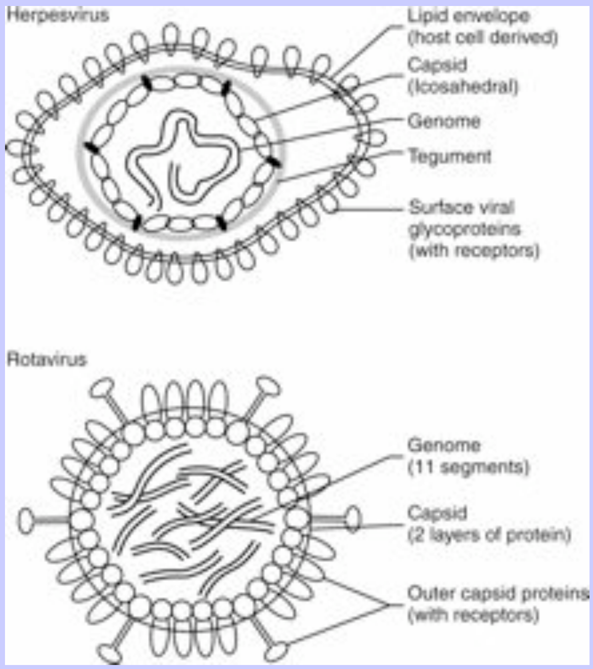
2.2.1.1 VIRUS STRUCTURE, TAXONOMY, AND REPLICATION

The fundamental structure of all viruses is a DNA or RNA genome enclosed by a coat of protein called the capsid (Figure 2.2-1). For viruses that are enveloped, the capsid is enclosed further by a host cell–derived lipid membrane into which viral proteins have been incorporated. In addition to protecting the viral genome, the capsid and other associated structural proteins (e.g., matrix proteins) are important for virus assembly,

packaging the viral genome, releasing the genome into a target cell, and for non-enveloped viruses, providing receptors that bind to host cells. For enveloped viruses the receptors are incorporated into the lipid membrane. The primary clinical significance of these features is that enveloped viruses, because of their fragile lipid membrane, are highly susceptible to inactivation by heat, desiccation, or detergents, and transmission typically requires direct exchange of body fluids, short distance aerosols, or arthropod vectors. In contrast, nonenveloped viruses (e.g., equine rotavirus) are resistant to physical inactivation, and environmental contamination is more likely to be a significant factor in their transmission.

The composition of the viral genome is an important basis for virus classification (Figure 2.2-2). The type of viral genome also determines the strategies required to replicate the genome and transcribe messenger RNA (mRNA) (Figure 2.2-3). Viral genomes may be single-stranded RNA, double-stranded RNA, single-stranded 75
DNA, or double-stranded DNA. The genomes of single-stranded RNA viruses may be of "positive" polarity in 76
which the genome also serves directly as mRNA for translation of viral proteins. To replicate genomes, these viruses must first synthesize a strand of complementary RNA that can be used as a template to replicate genomes and transcribe new mRNA. Retroviruses are a subset of single-stranded, positive polarity RNA viruses that use their RNA genome as template to produce double-stranded DNA, which in turn is used for the transcription of mRNA and new viral genomes. Single-stranded RNA viruses may also be of "negative" polarity in which the genome is antisense to mRNA, and synthesis of a complementary RNA strand is required to serve as mRNA and as template for new genomes. The clinical significance of these types of replication strategies is that they require polymerases and other enzymes not normally found in eukaryotic host cells. Eukaryotic cells, which exclusively use DNA as genetic material and as templates for mRNA transcription, use DNA-dependent DNA polymerases and DNA-dependent RNA polymerases for these functions, respectively. RNA viruses require RNA-dependent RNA polymerases to replicate or transcribe RNA, or RNA-dependent DNA polymerase (reverse transcriptase) to produce DNA from an RNA template. These unique viral enzymes are important targets for antiviral drugs because they can be used selectively to inhibit viral replication. The most common antiviral drugs currently available are nucleotide analogs that are used selectively by viral but not cellular enzymes and result in defective DNA or RNA.[17,18] Although most DNA viruses follow the eukaryotic pattern of replication and transcription, in many cases these viruses produce homologs of host cell enzymes that are sufficiently unique to make them selectively susceptible to nucleotide analogs. Additional targets for current and future antiviral agents are viral proteins used for translation and posttranslational protein processing.[17]

Figure 2.2-1 Schematic representations of basic viral structure. The basic structure of an enveloped virus is shown by the drawing of a herpesvirus. The basic structure of a non-enveloped virus is shown by the drawing of a rotavirus.



Viral polymerases and the genetic organization of viruses are also important for rapid antigenic variation and immunologic evasion. Viral RNA polymerases are low fidelity and lack proofreading functions and thus randomly will introduce errors into new RNA at an average rate of about one nucleotide mismatch per 10,000 bases copied.[19] Therefore in a population of viruses, virtually every individual virus differs slightly, and this population is referred to as a quasi-species. Although many of these mutations are neutral or even deleterious, in the face of selective pressures such as the host immune responses or antiviral drugs, this genetic plasticity allows rapid development of resistant virus populations.[20] Secondary structures or certain sequences in the viral genome may facilitate polymerase errors further at selected regions that are important for immune evasion, such as in sequences that code for neutralizing epitopes.[19] The genomes of some viruses, such as influenza, are comprised of separate segments, which allows reassortment of entire gene segments and sudden and dramatic changes in antigenicity.[21]

2.2.1.2

VIRUS LIFE CYCLE

All viruses are obligate intracellular parasites. Viral replication can occur only within living cells, and all viruses to some extent depend on the host cell synthetic machinery. The life cycle of all viruses includes the following steps: attachment to the target cell, entry into the cell, uncoating and release of the viral genome, transcription and translation of viral proteins, replication of the viral genome, assembly of new virions, and

release of progeny virions[15,16] (Figure 2.2-4). Although the biochemistry of these steps is beyond the scope of this discussion, recognizing that they are all specific, energy-requiring interactions between the virus and the host cell is important. The inability of the virus to interact appropriately with a cell at any of these steps prevents replication in that cell type and defines the tropism of the virus. Any of these steps are also important potential targets for antiviral drugs and host immune responses.

One of the most critical virus-cell interactions is attachment and entry. This initial step is one of the most important determinants of species susceptibility, host cell tropism, and is an important target for antiviral 76
antibodies that neutralize infectivity. Attachment and entry requires a specific interaction between a viral 77
receptor and a cell-surface protein that acts as the host cell receptor. Many viruses also require interaction with additional cell surface molecules (co-receptors) for successful attachment and entry. Influenza provides a good example of this process. The influenza virus hemagglutinin molecule binds to sialic acid residues of cell-surface glycolipids or glycoproteins. Binding induces a conformational change in the hemagglutinin protein, exposing a cleavage site to a host cell protease. Cleavage of hemagglutinin induces fusion of the viral envelope to the host cell membrane and release of the capsid into the cytosol.[22,23] Equine influenza does not infect human beings because the hemagglutinin molecules do not recognize human sialic acid molecules.[24] Within the horse, equine influenza infection is restricted to respiratory epithelial cells by the distribution of the appropriate host cell protease.[22] Viruses may infect other cell types by using a different host cell receptor for attachment and entry. Highly pathogenic strains of avian influenza are able to spread systemically because of mutations in the hemagglutinin that allow cleavage by host cell proteases found on cells outside of the respiratory tract.[22] Other ways in which a virus can infect multiple cell types are using a host cell receptor that is present on different cell types or infecting a single cell type that is present in different tissues (e.g., macrophages and vascular endothelium). Host cell receptors also may be present in an age-dependent fashion, 77
accounting for age-related differences in susceptibility to diseases such as polioencephalomyelitis and 78
rotaviral enteritis.[25,26]

Figure 2.2-2 Virus family classification based on genome composition and presence of envelope or absence of envelope. The relative size of the viruses to each other is also shown.

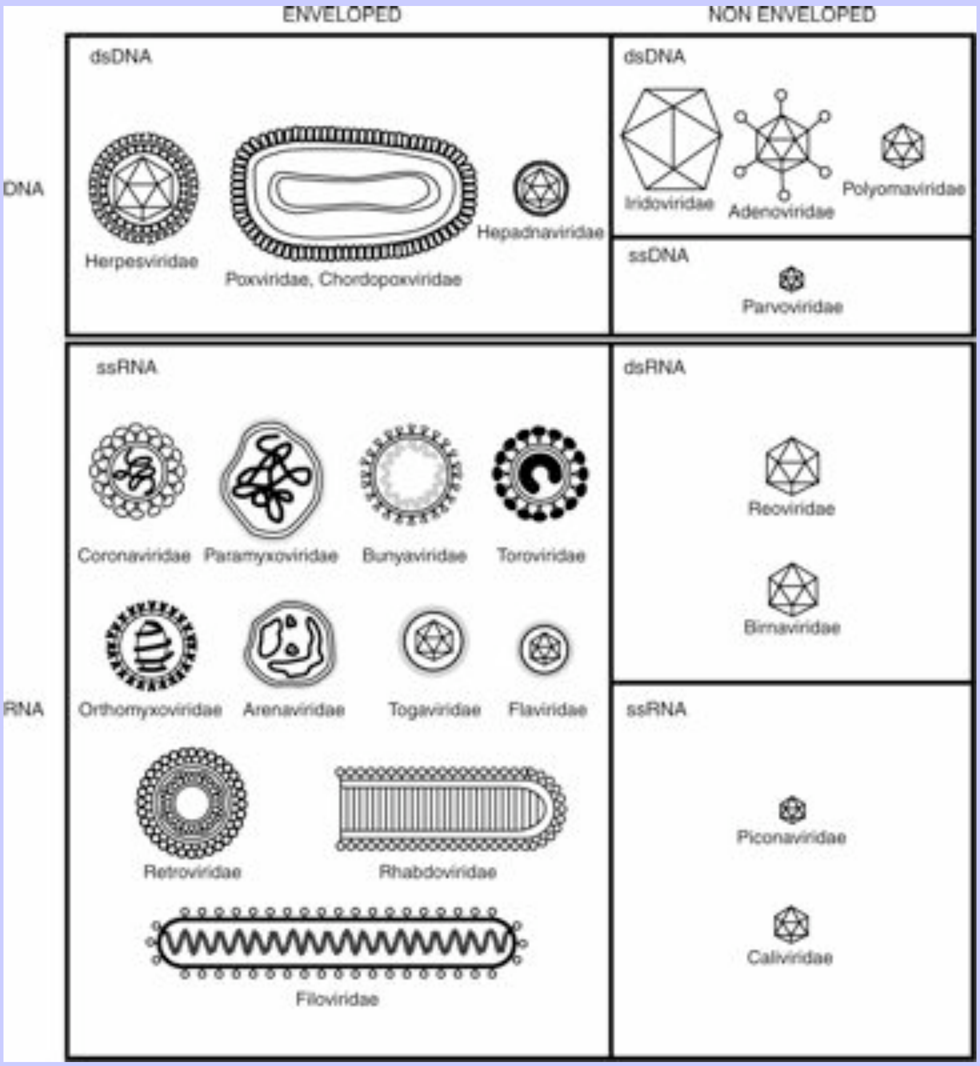


Figure 2.2-3 Summary of the main virus families that infect vertebrates, and general strategies employed by these viruses to produce mRNA for protein expression and to replicate genomes. Required intermediate molecules are indicated. *White arrows* indicate the need for unique viral polymerases, including RNA-dependent RNA polymerase and RNA-dependent DNA polymerase (reverse transcriptase). *Dark arrows* indicate the use of cellular polymerases or viral homologues of cellular polymerases. *ds* = Double-stranded; *ss* = single-stranded; *(+) for RNA* = positive polarity, polarity of RNA used for protein translation; *(+) for DNA* = coding strand, sequence same as for (+) RNA; *(– or +) DNA* = contains single strands of DNA of both polarities. (Modified from Baltimore D: Expression of animal virus genomes, Bacteriol Rev 35:235-241, 1971.)

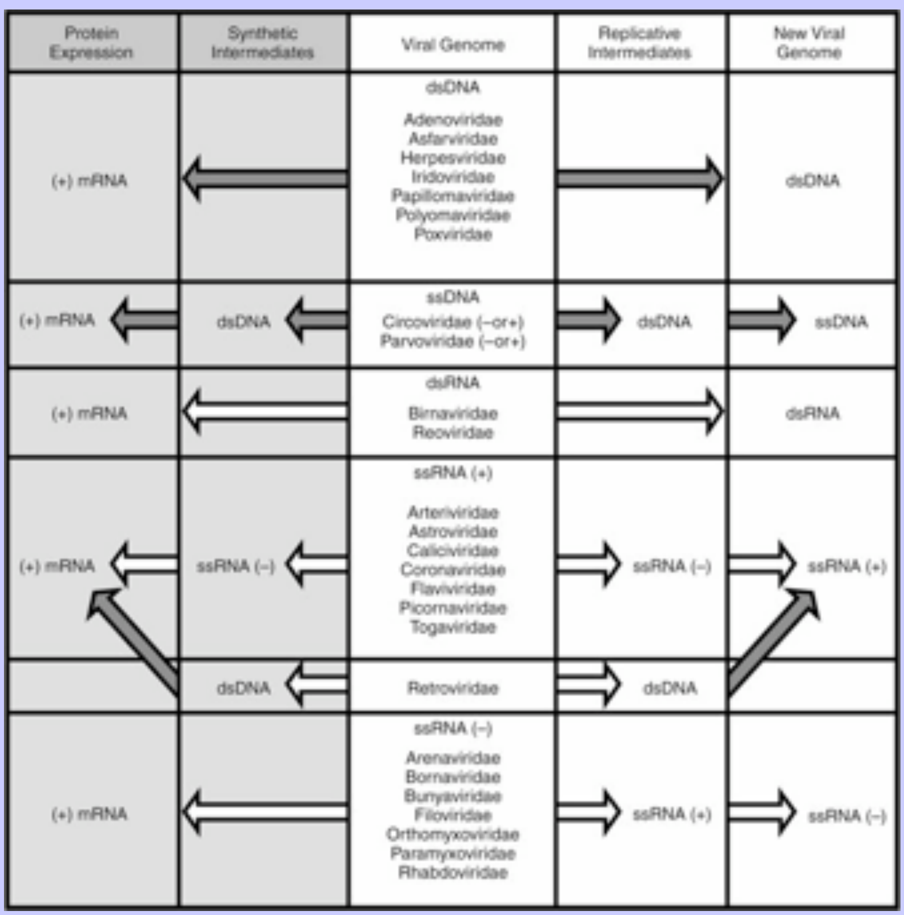
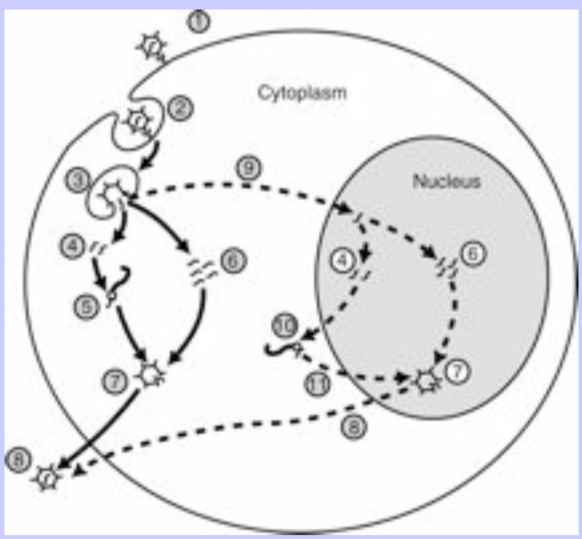


Once the viral nucleocapsid gains entry to the cytosol of the cell, the viral genome is released through the process of uncoating. After uncoating, depending on the genetic composition of the virus, the viral genome localizes to the appropriate regions of the cell for replication and mRNA transcription. DNA viruses typically replicate genomes and transcribe mRNA in the nucleus and then transport the mRNA to the cytoplasm for translation. RNA viruses typically replicate, transcribe mRNA, and translate viral proteins in the cytoplasm. These sites of replication account, respectively, for the location of viral inclusion bodies that are diagnostically useful in histopathologic sections. In general, the first viral proteins expressed are regulatory factors, enzymes, and polymerases required for initiation of viral gene expression and diversion of host cell resources to viral 78
replication. Subsequently, viral structural proteins are expressed and assembled with new viral genomes into 79
virions. Enveloped viruses require the additional step of acquiring a lipid envelope by budding the nucleocapsid through areas of the nuclear or plasma membrane into which viral proteins have been incorporated. Viruses then are released, usually in association with death of the host cell, into the extracellular space and blood. Some viruses such as herpesviruses and paramyxoviruses also may transfer progeny virions directly into an adjacent cell by inducing fusion between the two cells, a strategy that allows the virus to avoid contact with neutralizing antibodies in the extracellular space.

Figure 2.2-4 Schematic representation of the general virus life cycle. Both RNA and DNa viruses share the initial steps, including attachment *(1)*; entry/fusion *(2)*; and uncoating and release of viral genome into the cell *(3)*. *Solid arrows* indicate remaining steps for RNA viruses, which all occur in the cytoplasm, including transcription of mRNA *(4);* translation of virual proteins *(5)*; replication of the viral genome *(6)*; assembly of new virions *(7)*; and release of progeny virions *(8)*. *Dashed arrows* indicate steps for a DNA virus. The life cycle is similar except that the DNA genome is translocated to the nucleus *(9)* for transcription *(4)* and replication of viral genomes *(6)*. Viral mRNA is then translocated back to the cytoplasm for translation *(10)*, and newly synthesized viral proteins are translocated back to the nucleus *(11)* for assembly *(7)*; new virons are then released from both nuclear and cytoplasmic membranes *(8)*.



2.2.1.3 VIRUS-CELL INTERACTIONS

After a cell is infected, the process of viral replication may have a number of effects on the host cell. Viruses have evolved a number of strategies and host cell interactions to facilitate their own replication and circumvent host responses that may eliminate the infected cell. In general, virally driven effects favor viral replication, transmission, and persistence and often result in death or dysfunction of the infected cell. Cellular

or host responses generally favor control and elimination of the virus from the host. These responses may block viral replication, may initiate innate and specific host immune responses, and are frequently evident clinically as inflammation.

2.2.1.3.1 Cell Cycle and Viral Replication

Viral replication requires that the host cell support high levels of nucleic acid replication, mRNA transcription, and protein translation. The growth and division phase of the cell cycle (S phase) is most suited for this purpose. However, many cells infected by viruses already are differentiated fully and in the resting phase (G_0 or G_1 phase). Some of the more complex viruses, such as herpesviruses, poxviruses, and adenoviruses, have virally encoded proteins that activate the cellular systems for growth and division, thus manipulating the cell to create an environment favorable for viral replication. This ability allows tropism for cells that otherwise might not be able to support viral replication. The "immediate early" genes expressed by herpesviruses, which initiate viral replication in differentiated cells, induce progression of the cell cycle from G_0 to the S phase.[27,28] Other viruses, particularly the genetically simpler viruses such as parvoviruses, lack the ability to activate resting cells.[27,29] Thus their tropism is restricted to cells that naturally go through a growth and division phase, such as intestinal crypt cells and hematopoietic cells. Consequently, parvoviral diseases such as feline panleukopenia typically involve replication in the rapidly dividing cells of the intestine (diarrhea) and bone marrow (pancytopenias). If infection occurs in utero during development of tissues such as the cerebellum, neurologic disease also may be observed.

2.2.1.3.2 Cell Killing

Cells that replicate virus often are killed as a direct consequence of infection. One mechanism by which viruses kill cells is lysis, often associated with the release of progeny virions. Insertion of viral proteins into cell membranes, budding, direct toxicity of viral proteins, and diversion of normal host cell homeostatic processes to viral replication may result in death of the cell.[15,16,30] Viruses also may activate the cellular self-destruct mechanism of programmed cell death (apoptosis). Although cells may induce apoptosis to try to prevent completion of the virus life cycle, viruses also may use this mechanism to kill the cell and facilitate release of virions.[31]

2.2.1.3.3 Neoplasia

Viral infection can cause neoplastic transformation of infected cells. The most common examples in horses include warts (equine papillomavirus) and sarcoids (bovine papillomavirus). Unlike other species, virally induced invasive neoplastic diseases such as leukemia or lymphosarcoma have not been recognized in the horse. However, these types of diseases may be identified in the future. 79 80

Viral proteins that activate the cell cycle into the growth and division phases may lead to neoplastic transformation if expressed in a cell that is not killed by the infection. Papillomavirus infections induce epithelial neoplasms (fibropapillomata) using a virally encoded protein (E5 oncoprotein) that induces proliferation of normally quiescent cells and that presumably is needed for viral replication.[8] The E1A oncoproteins and immediate early proteins of adenoviruses and herpesviruses, respectively, are highly oncogenic in cells that do not allow full virus expression.[32,33] Adenoviral and herpesviral infections in horses currently are not recognized as oncogenic. The lack of oncogenic transformation by these viruses is most likely because abortive infections may not occur in vivo, transformed cells are always removed by the

immune system, or the requisite co-factors for transformation are not present. As an example of the role of co-factors, infection of human beings with human herpesvirus 4 (Epstein-Barr virus, the cause of infectious mononucleosis) is not associated commonly with neoplasia in North America or Europe, whereas infection with this virus in Africa is associated strongly with Burkitt's lymphoma and in China with nasopharyngeal carcinoma.[34]

Oncogenic retroviruses, including leukemia and sarcoma viruses, induce neoplastic transformation in several ways but in all cases do so by integration into the host cell genome and activation of cellular oncogenes.[35] Specifically, a retrovirus and its viral promoter sequences may insert upstream from and activate a normally quiescent cellular oncogene in the process of viral gene expression. Other retroviruses, such as the bovine leukemia virus, produce a virally encoded protein, *tax*, that transactivates and upregulates the expression of cellular oncogenes. These are believed to be the primary mechanisms of transformation by the leukemia viruses. Integration of the retroviral genome also may inactivate by insertion host cell repressors required to actively suppress the expression of cellular oncogenes. Some retroviral genomes, such as those of the rapidly transforming sarcoma viruses, may transform the cell by acquiring cellular oncogenes that are then co-expressed along with other viral gene products during replication.

2.2.1.3.4

Interference With Differentiated Cell Function

Although not described in horses and still poorly documented in other species such as human beings, some viral infections are theorized to play a role in chronic diseases such as diabetes and obesity. For example, the hepatitis C virus may infect the B cells of the pancreas and interfere with the production of insulin.[11] In experimental infections of rodents, canine distemper virus and Borna disease virus cause obesity, possibly by infection of the hypothalamus and downregulation of leptin receptors.[12] Although the role of viruses in these types of infections is still controversial, advances in the detection of viruses are likely to uncover unusual and previously unsuspected roles for viruses in chronic diseases, including those of horses.

2.2.1.3.5

Interactions With Host Immune Responses

One of the main obstacles to successful viral replication in vivo is the host immune response. In response to infection, cells can react in a number of ways to block viral replication, initiate the expansion of specific antiviral immune responses, and target the infected cell for immunologic recognition and destruction. As a result, many viruses have developed counterstrategies to block cell signals that promote these host cell responses.

Interferons induce the expression of a number of cellular proteins that inhibit viral replication in the cell. Secreted interferons similarly impart resistance to viral replication in adjacent cells, and are an important mechanism for controlling the local spread of infection. Some viruses, including paramyxoviruses, adenoviruses, and herpesviruses, produce proteins that interfere with the cell signaling mechanisms required for the expression of interferon-induced proteins.[36,37]

One of the most important systems for recognition of virally infected cells by cytotoxic lymphocytes is endocytic processing of viral proteins followed by expression of the resultant viral peptides on the cell surface complexed with major histocompatibility complex (MHC) class I molecules. Viral products may interfere directly with the processing, transport, or cell surface expression of MHC I molecules or viral

peptides, thereby preventing recognition by cytotoxic, $CD8^+$ T lymphocytes.[36,38] In antigen-presenting cells, cell surface expression of viral peptides with MHC II molecules to immune regulatory cells, mainly $CD4^+$ helper T lymphocytes and B cells, is required for initiation and upregulation of antibody and cell-mediated antiviral immune responses. Similar interference with the processing, transport, or cell surface expression of MHC II molecules or viral peptides can interfere with antiviral immune responses.[36] In addition, some herpesviruses also have been shown to interfere with recognition of virally infected cells by natural killer cells, an early, nonspecific cell-mediated immune response.[39]

An interesting and more recently recognized viral mechanism for interference with host immune responses is the use of virally encoded cytokine mimics. Cytokines are critical cell signaling molecules that coordinate and regulate the development of host immune responses. Some viruses, including poxviruses, herpesviruses, and adenoviruses, express cytokine homologs that mimic and interfere with the activity of interferons, interleukin-1, interleukin-8, interleukin-10, tumor necrosis factor, epidermal growth factor, and granulocyte-macrophage colony-stimulating factor.[36,40] Although the role of these homologs in natural disease is not clear, experimentally they can modulate immune responses and affect disease severity.[36]

80
81

2.2.1.3.6 Virologic Latency

At the host level, viruses may use several mechanisms to establish persistent infections and avoid immune clearance. Some persistent infections are characterized by continual replication despite the presence of antiviral immune responses. If these types of persistent infections are subclinical, they often are described as clinically latent. However, the viral dynamics at the host level should be differentiated from events at the cellular level. In cells, virologic latency is a specific type of cell interaction and an important mechanism of persistence for some viruses. Virologic latency is defined as the presence of a viral genome that is not producing infectious virus.[41] The genomes of latent viruses also are transcriptionally suppressed and translationally silent so that no viral proteins are expressed that may identify the cell to the immune system as infected. The definition of latency also stipulates that on reactivation, viral gene expression and the production of infectious progeny virions can be resumed, differentiating latently infected cells from cells infected with defective viruses.

The classic latent infection is that of the herpesviruses. For the α herpesviruses, such as EHV1 and EHV4, latent infections are established in the nuclei of sensory neurons and can be maintained indefinitely, and infected animals serve as the reservoir of the virus.[42–44] The only detectable viral gene products in latently infected neurons are a small RNA message called latency-associated transcripts, which are required for maintenance of latency.[41] On reactivation, viral nucleic acids are translocated across synapses to epithelial cells of the nasopharynx, which produce infectious virus. In adult horses the amount of viral replication in the nasopharynx is usually not sufficient to result in clinical disease.[44] The stimuli that induce reactivation are poorly defined, but reactivation can be induced by immunosuppression (e.g., corticosteroids) and presumably by other stressors such as pregnancy, transport, and social stress.[44,45]

2.2.2 Mechanisms of Disease: Virus-Host Interactions

Viral interactions with individual cells are the basis for viral pathogenesis. However, for the whole animal, the severity of disease, or whether infection even results in clinical disease at all, is a much more complex interaction between the classic triad of virus, host, and environment. More specifically, these factors include

viral virulence, viral spread within the animal, the intensity of direct and immune-mediated pathologic response elicited by the virus, and the ability of the virus to avoid clearance by the host. Other than the virulence of the virus, which is strictly a property of the virus, the other virus-host interactions can be influenced by the age and genetics of the host and by environmental factors such as stress and nutrition. These factors account for the observation that considerable variation in disease signs can occur among a group of animals infected with the same viral strain.

2.2.2.1 VIRAL VIRULENCE

Certain strains of a virus are well recognized as causing more severe disease. Although many host factors may influence the severity of clinical disease, virulence per se is strictly a property of the virus. The main properties of a virus that may affect virulence include host cell tropism and replication rate. A tropism change that leads to involvement of additional tissues or facilitates virus spread generally results in more severe disease. The systemic spread of highly pathogenic avian influenza strains described earlier is one example. Outbreaks of EHV1 abortion or neurologic disease strongly suggest that EHV1 strains exist that have a tropism for these tissues compared with EHV1 strains that cause respiratory disease. However, the appropriate studies have not been performed yet to determine the exact basis for this observation. Limited studies of EHV1 genetics and virulence in mouse models have not identified differences between the abortigenic, neurogenic, and respiratory strains.[46] However, the severity of EHV1 respiratory disease in experimentally infected foals can be decreased by deletion of genes that facilitate cell-to-cell spread.[47]

An increase in the viral replication rate usually is associated with an increase in virulence, presumably because of the greater number of infected cells and amount of tissue damage. The virulence of equine infectious anemia virus strains can be correlated directly to plasma virus titers and numbers of infected cells, without any changes in tropism.[48,49] The molecular basis for the increased replication rate is not clear but most likely is caused by variation in viral regulatory sequences and proteins.[50,51]

2.2.2.2 SPREAD OF INFECTION IN THE HOST

Viral infections generally are regarded as localized or systemic. Localized viral infections are those that are restricted to a single organ system, often at the site of entry. Because infection of the tissue is direct, the incubation period for localized viral infections is usually short, often only a few days. Many infections of the skin or mucosal surfaces are localized, and examples in the horse include infections with enteric rotavirus and 81
influenza. For influenza, virus is inhaled into the nasopharynx and replicates in epithelial cells of the upper 82
respiratory tract and trachea. Virus is not present in the blood or tissues outside of the respiratory tract. In general, viruses remain localized because they lack the receptors to infect cells of other tissues or circulating cells such as monocytes or lymphocytes that can disseminate the virus. Some viruses are temperature sensitive and remain localized because they are unable to replicate efficiently at core body temperatures. EHV3, the cause of coital exanthema, is restricted to the surface of the genitalia in horses because of its temperature sensitivity.[52] EHV1 and EHV4 are not temperature sensitive, however, and systemic infection may occur with these viruses. The feline respiratory herpesvirus is also temperature sensitive and normally is restricted to the cooler mucosal surfaces. However, hypothermia may lead to dissemination and multiorgan infections.[53] Temperature sensitivity is also a means by which some viruses, such as equine influenza and infectious bovine rhinotracheitis virus, may be attenuated for use as modified-live intranasal vaccines. Infection by the vaccine strain is limited to the cooler mucosal surfaces; the inability to spread systemically prevents sequelae such as abortion and pneumonia.[54,55]

Systemic infections are those in which virus is disseminated to multiple tissues by blood or lymph. This viremia may exist in the form of cell-free virions in the plasma or lymph or may be cell-associated in circulating blood cells, usually monocytes or lymphocytes. The classic paradigm for a systemic infection is infection of mice with ectromelia virus[56] (Figure 2.2-5). Localized viral replication first occurs at the site of entry and in regional lymph nodes. Depending on the level of replication, clinical disease may be present. The virus then enters the blood or lymphatics and spreads to other tissues such as spleen and liver, in which clinical disease may occur. Virus is amplified and then released again for a second, usually higher-titered, viremia that further disseminates the virus to other organs. Each viremic episode is associated with a febrile response and is the basis for the biphasic fever response associated with some viral infections. Because systemic infections require multiple steps, the incubation periods are longer than for localized infections, typically 1 to several weeks. Infections in the horse by eastern, western, or Venezuelan equine encephalitis virus closely follow this paradigm. Localized viral replication occurs at the site of entry (mosquito bite) followed by viremia and dissemination to the central nervous system.[57] For most horses, even nonvaccinated horses, dissemination is controlled before infection of the brain, and neurologic disease is a rare outcome of infection. A variation on the theme is infection of horses with EHV1. The most common clinical disease associated with EHV1 infection is rhinopneumonitis caused by a localized infection of the nasopharyngeal mucosa.[58] In almost all cases a cell-associated viremia also occurs in lymphocytes, but in most infected horses this does not result in disease. However, in some cases, viremia is associated with infection of endothelial cells, and in the pregnant mare vascular damage to the uterus and placenta may lead to abortion.[58,59] Similarly, infection of the vascular endothelium in the central nervous system results in neurologic disease.[60]

Some viruses also may spread in the host through nerves. In the horse, rabies is the best known infection that relies on neural spread. Following local replication in myocytes at the site of entry, usually a bite wound, rabies virus ascends peripheral nerves into the central nervous system, where it replicates in neurons, and then egresses by way of cranial nerves to the salivary gland.[61] EHV1 and EHV4 establish latency in the nuclei of sensory neurons that innervate the nasopharynx and reach the nucleus by ascending nerve axons. Similarly, on reactivation, these viruses egress back down the axon to infect epithelial cells.[43,62]

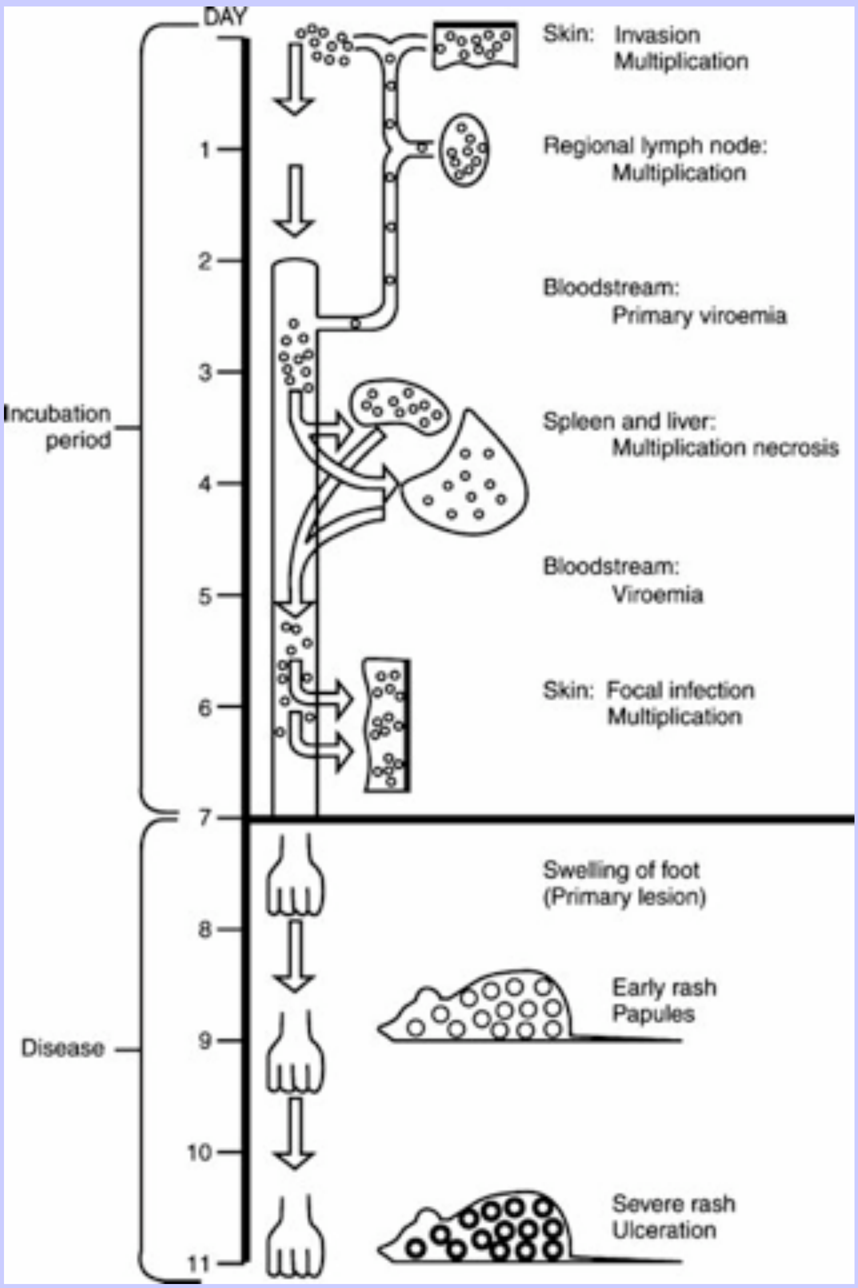
2.2.2.3 VIRAL PATHOLOGY

Once a virus reaches a target organ, virally mediated cell death is the fundamental source of pathologic response, disease, and clinical signs observed by the veterinarian. Despite the great complexity of virus-host interactions and the many factors that influence the expression of clinical disease, in actuality viruses have a limited number of ways by which to cause infection. Cells and tissues may be destroyed directly by cytolytic viral infections or by infections that affect the differentiated function of target cells (e.g., neoplasms and immunodeficiencies). Viral infections of organ systems with bacterial flora (e.g., intestinal and respiratory tracts) can disrupt the normal barrier functions of these organs and result in secondary bacterial infections and toxemia that may contribute significantly to the pathologic response. Cell death and pathologic response also may be caused by host immune responses specifically directed against virally infected cells or by indiscriminate inflammatory responses. Virally induced autoimmune diseases have not been described in horses but are another potential source of pathologic response that may be identified in the future.

For most of the clinically important viral diseases of horses, disease manifestation results from some combination of cytolytic infection and immune-mediated tissue destruction. The relative contribution of these mechanisms is primarily a function of viral virulence and host factors that influence the type and intensity of immune responses. The predominant mechanism of pathologic response also can vary with different stages of

the same disease, as seen in acute versus chronic equine infectious anemia. In acute disease, most of the diseasea manifestation is caused by direct viral damage and cytokines, whereas in chronic disease, immune complex–mediated anemia and glomerulonephritis become more significant. 82 83

Figure 2.2-5 Schematic representation of the pathogenesis of mousepox (ectromelia), illustrating the classic paradigm for the events in a systemic infection. (Fenner F: The pathogenesis of the acute exanthems, *Lancet* 255:915, 1948.)



2.2.2.3.1 Direct Viral Pathology

The most straightforward cause of damage and disease in an organ system is for the virus directly to kill or cause dysfunction in the infected cells. As described previously, cell death may be caused by cytolysis resulting from viral replication and interference with normal cell homeostasis or by initiation of apoptosis. Cell dysfunction usually is observed as neoplastic transformation, although more vague effects on other differentiated cell functions, such as insulin secretion, remain possibilities.

The disease associated with a given viral infection is related to the affected organ system(s), the number of cells destroyed, and the sensitivity of the affected organ system to dysfunction. If the number of infected cells is not sufficient to lead to clinically significant organ dysfunction, then the result is a subclinical infection. Vaccination and naturally acquired immunity are important factors that limit the number of 83
infected cells. However, epidemiologically these infections may still be important because these animals 84
may still be infectious. When enough cells are infected to lead to overt organ dysfunction, then clinical disease becomes apparent. The threshold for clinically significant damage varies considerably between organs and the types of cells. EHV1 infections of the respiratory epithelium, which has a large number of cells with a high turnover rate, produce mild clinical disease even with a high rate of infection. On the other hand, much more significant clinical manifestations of EHV1 infection such as abortion and neurologic disease are caused by infection of a few endothelial cells because minimal vascular damage can lead to thrombosis, ischemic necrosis, and damage to large amounts of tissue. If viral infection results in neoplastic transformation of a cell type, then disease may progress according to the characteristics of the neoplasm, whether or not the virus remains associated with the tumor.

Of particular importance are infections of the respiratory and intestinal tracts that contain normal bacterial flora and have important barrier functions to prevent access of bacteria and toxins to deeper tissues. Consequently, complications of bacterial infection and toxemia are important secondary problems of viral infections.[63,64] For example, upper respiratory viral infections damage the ciliated epithelial cells that function to move mucus and other respiratory secretions outward and provide a barrier between the mucosal bacterial flora and the underlying subepithelial tissues. Damage to this barrier may lead to opportunistic bacterial pneumonias by normal bacterial flora such as *Streptococcus equi zooepidemicus* or *Mannheimia haemolytica* in horses or cattle, respectively.

2.2.2.3.2 Immune-Mediated Viral Pathology

In most viral infections, immune-mediated pathologic response contributes significantly to disease and in some cases may be the predominant cause of disease manifestation. This paradigm has been documented elegantly in classic experiments with lymphocytic choriomeningitis virus infections of mice in which immunodeficient mice develop persistent infections but do not develop disease and do develop disease if their immune systems are reconstituted.[65] Details of equine immune and inflammatory responses are covered in detail in Chapter 1 and are described in this section only in general terms and as they relate to viral infections.

The primary antiviral immune responses initiated in viral infections include natural killer cells, virus-specific cytotoxic ($CD8^+$) T lymphocytes, and to a lesser extent antibody-mediated lysis of infected cells (antibody-directed cellular cytotoxicity, complement fixation, and phagocytosis by macrophages and neutrophils). These immune responses detect and selectively kill virally infected cells and are a significant

cause of cell death. Indiscriminate inflammatory responses also may kill uninfected cells in the vicinity of infected cells, primarily from activation of monocytes and granulocytes with release of a wide array of cytotoxic molecules (e.g., lysozyme, proteases, lipases, and oxygen radicals). Secondary bacterial infections greatly exacerbate indiscriminate tissue damage, not only from the direct effect of bacterial toxins but also because of extensive recruitment of neutrophils and complement, which are highly nonselective components of the antibacterial immune response.

Antibody-mediated immune complex hypersensitivity reactions also may play a major role in the genesis of viral disease. Antibodies bound to soluble viral antigens fix complement and opsonize neutrophils, again leading to indiscriminate cell and tissue destruction. Viral antigens may be on the surface of cells, such as erythrocytes or platelets, resulting in immune-mediated anemia and thrombocytopenia, respectively.[66] When viral antigen is in excess relative to antibody, circulating immune complexes are formed that can be deposited in the capillary beds of tissues such as joints and renal glomeruli. In chronic equine infectious anemia virus, with persistent viral replication and antigenemia in the presence of antiviral antibodies, these mechanisms are primarily responsible for the characteristic lesions of anemia, thrombocytopenia, and glomerulonephritis.[66,67] Nonneutralizing antiviral antibodies actually may serve to increase the number of infected cells and the severity of disease through the mechanism of antibody-dependent enhancement. This enhancement occurs when antibodies bind to the virus and facilitate attachment and entry into Fc receptor–bearing cells such as macrophages by serving as a form of alternative receptor.[68] Antibody-dependent enhancement has been shown to be involved in the pathogenesis of a number of diseases, including feline infectious peritonitis,[69] human respiratory syncytial virus,[70] and dengue hemorrhagic fever.[71]

Soluble inflammatory mediators released by infected cells and inflammatory cells in response to viral infections are also significant contributors to clinical signs and disease manifestation. These mediators include a wide array of cytokines, interleukins, and other proinflammatory molecules with potent systemic and local effects. The most evident of these is the febrile response caused by interleukin-1 released by macrophages in response to virally infected cells. Increased levels of other soluble factors, including interferons, interleukins, transforming growth factor, and tumor necrosis factor are also present in many viral infections.[72,73] These cytokines are primarily proinflammatory and immunoregulatory and are generally important for the control of viral infections but also can be responsible for many of the nonspecific clinical signs of viral infection such as depression, malaise, and in chronic infections, cachexia. 84
Soluble mediators also may have important local effects. Vasoactive factors such as prostaglandins and 85
leukotrienes cause edema and swelling. In equine infectious anemia virus, tumor necrosis factor α, transforming growth factor β, and interferon-α have been shown to suppress hematopoiesis and contribute to the development of anemia and thrombocytopenia.[74]

2.2.2.3.3 Autoimmunity

Although not described in horses, viral infections in other species can induce immune-mediated responses to host cell antigens and autoimmune diseases. The best documented human autoimmune disease suspected to be initiated by viral infections is the Guillain-Barrè syndrome, in which infection with cytomegalovirus or Epstein-Barr herpesvirus elicits antinerve ganglioside immune responses and demyelinating disease.[75] Postinfluenza myocarditis is an occasional sequela in horses and human beings and is a potential autoimmune disease. Although no direct evidence supports this theory, influenza virus is not identified consistently in affected heart muscle and the pathogenesis is not known.[76]

2.2.2.4 IMMUNE AVOIDANCE

A key requirement for viruses to be maintained in nature is to persist successfully in a reservoir host (if the reservoir is an infected animal) and to be transmitted to another susceptible host. One of the most important obstacles to persistence and transmission is detection and elimination by the host immune system. Transmission to a new host also may require that the virus avoid preexisting immunity from prior natural exposures or vaccination. Within the host, rapidly replicating viruses such as influenza may shed and transmit virus before the host can mount specific antiviral immune responses. Herpesviruses avoid detection during latency by not expressing any viral proteins. For persistent viral infections that continually replicate within a host, such as retroviruses, evasion of developing immune responses is necessary. Immunodeficiency viruses may cripple antiviral immune responses by directly infecting immunoregulatory $CD4^{+}$ T lymphocytes. As described previously, many other viruses can dysregulate host immune responses by expressing cytokine mimics.

One of the most important mechanisms of immunologic avoidance is antigenic variation in which neutralizing viral antigens are altered so that they are no longer recognized or accessible by host immune responses. The most important of these antigens includes viral proteins bound by neutralizing antibodies (e.g., virus receptors) and any peptides presented in the context of MHC I or II cell surface molecules for recognition by cytotoxic ($CD8^{+}$) T lymphocytes or helper ($CD4^{+}$) T lymphocytes, respectively. Antigenic variation is generated by nucleotide errors during transcription or replication, which result in amino acid substitutions in the relevant epitopes. This process is facilitated by viral polymerases that are inherently error-prone and lack proofreading functions and by placing the sequences for the relevant epitopes adjacent to other genomic sequences or structures that further predispose to transcriptional errors.[19] Other mechanisms by which some viruses may modify their antigenicity is through intramolecular recombination/duplication or reassortment of segmented genomes (e.g., influenza and African horse sickness).[19,21] For reassortment, co-infection of a single cell with genetically different virions may result in a progeny virion with segments derived from both virions and a major change in antigenicity. In influenza these are called antigenic shifts, and the radical change in the antigenicity of the virus may render preexisting immunity in the host population ineffective at preventing outbreaks of disease with high morbidity and mortality.[21] Viruses also may facilitate the production of nonneutralizing antibodies that sterically interfere with the ability of neutralizing antibodies to bind. Although the mechanism of antigenic variation is primarily random, immunologic selection determines which variants successfully emerge and are capable of replicating within the host or the host population.

2.2.2.5 HOST GENETICS

Genetic differences in susceptibility to disease have been well documented. In an outbred population of animals, the considerable variation in the type or severity of clinical disease is well recognized, even when animals are infected with the same virus strain and have no recognizable differences in other factors such as age, challenge dose, nutrition, and general health status. Conversely, highly inbred populations may be more uniformly susceptible to a viral disease.[77] Thus inbreeding can pose problems for endangered species, such as Przewalski's horse, or other populations with limited genetic variability, which may incur high rates of morbidity or mortality if the animals are infected with a virulent virus.

Although in many virus-host interactions the basis for genetic resistance to disease is not well defined, host genetics have been shown to affect the tropism of the virus and influence the type and intensity of immune

responses to a viral infection. In human immunodeficiency virus infections, genetically determined absence or presence of certain co-receptors has a significant effect on susceptibility to disease.[78,79] Immunologically, host genetics defines the repertoire of antigen-specific recognition molecules (antibodies and T cell receptors) and antigen-presenting molecules (MHC I and II). Consequently, genetically different animals respond to different subsets of viral antigens. The relative inability to react to a neutralizing epitope prevents or delays effective 85
control of viral replication.[80] Different subsets of viral antigens may favor the development of a type 1 T 86
helper cell (cell-mediated) or type 2 T helper cell (antibody-mediated) immune response, which has implications for the ability to control infection and for immune-mediated pathologic response.[81–83]

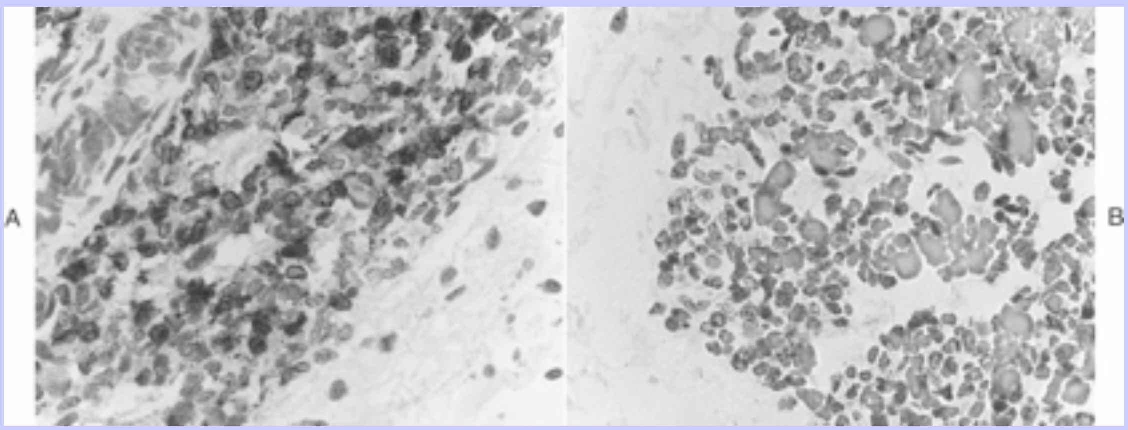
2.2.3 Advances in the Diagnosis of Viral Diseases

The diagnosis of viral infections traditionally has relied on the detection of antiviral antibodies by serologic tests and the direct demonstration of virus by isolation in cultures of living cells or in laboratory animals. Although these principles are still the foundation for the diagnosis of viral diseases, recent molecular biology advances have improved the clinical use of viral diagnostics greatly.

The sensitivity and specificity of antibody testing has been enhanced by the recombinant viral proteins or peptides for use as antigens in serologic tests. One example is the use of recombinant antigens in antibody tests for equine infectious anemia virus. The replacement of whole-virus antigen preparations with recombinant viral proteins has improved the sensitivity and specificity of the agar gel immunodiffusion (Coggins) and enzyme-linked immunosorbent assay tests.[84,85] The improvement in specificity is especially important when screening for a low-prevalence disease in which the predictive value of a positive result is low, as is the case for equine infectious anemia in the United States.

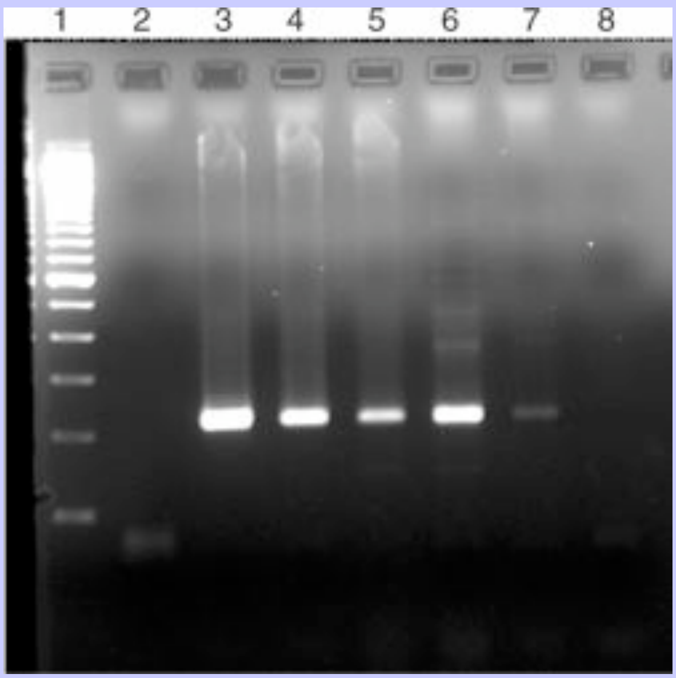
However, the greatest advances have been in the area of detection of virus in clinical specimens. The clinical utility of traditional methods of virus isolation in cell culture often is limited by the sensitivity, specificity, predictive value, or the length of time needed to perform this type of assay. Another significant limitation of virus isolation, particularly for the more labile enveloped viruses, is the requirement for viable virus, which may be compromised by autolysis or transport to the laboratory. In many diagnostic laboratories, virus isolation in cell culture has been replaced by immunohistochemistry and the polymerase chain reaction (PCR), both of which are sensitive and specific tests that can be completed within a day or two. Immunohistochemistry is a method that detects viral antigens in formalin-fixed tissue samples. Although immunohistochemistry technology has been available for many years, this assay has become more widely used because of improvements in the methods for antigen retrieval and the greater availability of antiviral monoclonal or polyclonal antibodies. The aldehydes in formalin cross-link proteins during the fixation process and prevent the recognition of epitopes by antibodies. For many viruses, reliable protocols now have been established that use carefully controlled protease digestion of the tissue sections so that the availability of epitopes is restored.[86] The tissue sections then can be incubated with antiviral antibodies, and bound antibodies can be visualized with a variety of colorimetric systems (Figure 2.2-6). The specificity of immunohistochemistry depends highly on the antiviral antiserum and has been improved greatly by the availability of antiviral monoclonal antibodies and recombinant viral proteins that can be used to generate monospecific antisera.[87–89]

Figure 2.2-6 Immunohistochemistry for equine herpesvirus in tissues of an aborted equine fetus. Panel A is a section of lung stained with anti-EHV antibodies. Bound antibodies are visualized with a secondary antibody conjugated to horseradish peroxidase that when reacted with the chromogen develops a visible precipitate in the cytoplasm of infected cells. Panel B is a negative control, which is a section of lung from the same fetus stained with an isotype-matched antiserum that does not contain anti-EHV antidodies; no precipitate is visible.



The polymerase chain reaction (PCR) assay is a nucleic acid amplification method that detects viral DNA or 86
RNA extracted from fresh or formalin-fixed tissue samples. Only a few years ago the techniques used to purify 87
nucleic acids and perform the PCR reaction were limited by expense and practicality to the research laboratory. However, the simplification and commercialization of these procedures has made this type of test economical and clinically useful for diagnostic laboratories.[90,91] The PCR test uses oligonucleotide primers and a thermostable DNA polymerase (Taq polymerase) to amplify exponentially the viral nucleic acids. The basis for specific amplification in the PCR assay is the sequence of the oligonucleotide primers, which are produced synthetically to be complementary and thus bind to the viral nucleic acid sequences. To produce complementary primers, the sequence of the viral DNA or RNA must be known. Consequently, this assay is only useful for testing for viruses that have been sequenced, and in the past, sequence data limited the ability to design PCR primers. However, because of advances in the technology for sequencing and database management, virtually all of the significant equine pathogens now have complete sequence data available. At the end of the PCR procedure, the amplified nucleic acids, that is, a positive result, are visualized most commonly with agarose gel electrophoresis in which the amplicons in the gel are viewed with a fluorescent dye, and the product presumptively is confirmed as the correct one based on its molecular size (Figure 2.2-7).

Figure 2.2-7 Analysis of PCR reactions for equine infectious anemia virus. PCR products are electrophoresed in an agarose gel. DNA in the gel is stained with ethidium bromide and visualized with ultraviolet light that causes the DNA to fluoresce and appear as white bands in the gel. Lane *1* is a size standard to determine the size of the DNA amplicons. Lane *2* is a negative control, and the lane *3* is a positive control. The samples in lanes *4, 5, 6*, and 7 are positive; the sample in lane *8* is negative.



Immunohistochemistry and PCR are now routine tests that generally are sensitive, specific, and rapid. However, care must be taken not to make assumptions about the performance characteristics of new tests. For example, although PCR assays are often more sensitive than virus isolation, this is not automatically true. The sensitivity and specificity of any new test must be evaluated individually and with respect to the performance of the previous test. Also, the significance of any virus identified in a specimen still must be interpreted in the context of the pathogenicity of the virus and clinical disease, regardless of the method used to detect the virus.

2.3—Internal Parasite Infections*

Maureen T. Long

Horses serve as hosts for numerous parasites that induce a wide range of pathologic and immunologic responses,[1] including hypersensitivities and other forms of immunopathology. Immune responses leading to protective resistance against reinfection occur, but the level of this resistance is most often incomplete. Mechanisms associated with these responses have not been investigated extensively in the horse, but information is available from other host-parasite systems that is relevant to the horse. The purpose of this section is to acquaint the reader with contemporary thoughts on host-parasite interactions. Because of their prevalence, major importance to equidae, and information available, coverage is limited to helminth parasites that occur in most developed and nontropical countries.

2.3.1

Parasite-Induced Lesions

Infection with most metazoan parasites results in inflammation and structural and functional changes of the organs invaded, the outcome being an alteration of the host's physiologic state. The degree of alteration depends on the existing physiologic condition of the animal, which is dictated to a great degree by its age, nutritional status, and previous immunologic experience with the parasite. The numbers of parasites introduced and the specific parasite also affect the degree of physiologic change that occurs. When these factors favor major alterations, the results are readily identifiable clinical signs of infection. Subclinical infections, although less apparent, are potentially important to the general health of the animal and continued transmission of the agent. The pathophysiologic effects of infection by ectoparasites, helminths, and microorganisms are in many cases similar. Abnormalities in weight gain, skeletal growth, reproduction, and lactation may result from infections with any of these agents. These changes often are related directly to parasite-induced anorexia, disruption of metabolic processes, and anemia. An understanding of the morphologic and biochemical lesions produced by specific parasites clarifies the role of these agents in clinical and subclinical conditions associated with the infections. A majority of detailed studies on the pathophysiology of parasitic infections have been conducted in 89
laboratory animal models and domestic animal species other than the horse.[2] However, the classical pathologic 90
effect of parasitic infections of the horse has been reviewed.[3,4] The following discussion outlines some recent observations on host-parasite interactions that may be significant to equine medicine. Examples of host-parasite interactions responsible for alterations in host homeostasis are presented as they relate to the gastrointestinal tract, lungs, and skin.

2.3.1.1 GASTROINTESTINAL TRACT

Internal parasites are most important to equine health as mediators of gastrointestinal symptoms such as colic and diarrhea. Although almost all internal parasites have been implicated inferentially as causative agents of colic at some time, large strongyles, principally *Strongylus vulgaris* and to a lesser extent *Parascaris equorum*, classically have been considered major pathogens. Details of the pathogenesis of colic associated with migration of *S. vulgaris* through the mesenteric arteries and the resultant thrombosis, infarctions, and necrosis of the intestine have been described in detail elsewhere.[3,4] Although this condition has been well described, some points are particularly noteworthy. Histologic studies of experimentally infected parasite-free pony foals during the initial stages of the infection indicate that the severity of the lesions produced in the intestine cannot be attributed solely to mechanical disruption caused by larval migrations and that these larval stages induce some biologic amplification system within the mucosa, which results in the degree of inflammation observed.[5] Although the mechanisms involved in this response have not been investigated, the histologic nature of the lesion is characteristic of an Arthus reaction, suggesting an involvement of the immune response. Other experimental studies using the parasite-free pony–*S. vulgaris* system have implicated the immune response in the mediation and regulation of the arterial lesions produced by this parasite. Passive transfer of immune serum, but not normal serum, reduced the severity of arteritis and clinical signs associated with experimental infections without reducing the numbers of parasites that developed in these ponies. However, treatment with immune serum also induced an anamnestic eosinophilia and significant perivascular infiltration of eosinophils in the cecum. The reduction in intravascular lesions may have been associated with an inactivation of parasite-secreted inflammatory factors by antibody or serum enzymes. This serum also may have contained nonspecific host-derived antiinflammatory substances. The exacerbation of the eosinophil response may have been associated with the formation of immune complexes. Although the mechanisms are unknown, the results suggest that the immune response may simultaneously modulate and potentiate inflammation. Larvicidal treatment of *S. vulgaris*–infected horses and killing of intravascular larvae has been postulated to release a bolus of antigenic factors from these larvae within the mesenteric vasculature, resulting in an exacerbation of arterial and intestinal lesions and colic. Experimental testing of this hypothesis indicates that this phenomenon does not occur and further that viable larvae are necessary to maintain the arteritis and eosinophilia seen.[6,7]

P. equorum–associated colic in foals has been related to intestinal impaction and rupture and is not considered to be of major significance in adult horses.[8] However, ascarid nematodes are particularly potent sources of allergens, and conceivably the hypersensitized mature horse may respond to low-level infections by this parasite. Observations made in the author's laboratory are noteworthy in this regard. Two mature *Parascaris*-free adult horses were inoculated intradermally with less than 90 μg of saline-soluble somatic extract of adult *P. equorum* to test for immediate hypersensitivity to this antigen. Both horses experienced an immediate systemic response and colic. One of the horses died within 3 hours of intradermal inoculation. Necropsy results were consistent with the diagnosis of colitis X. Because of the allergic potential of ascarid nematodes and the sensitivity of the equine gut to immediate hypersensitivity reactions, this potential is worthy of further characterization and consideration.

Recent clinical observations have piqued an interest and concern over the pathogenic potential of infections by *Anoplocephala perfoliata*. Case reports have described cecal ruptures and intussusceptions of the cecum and colon associated with these infections.[9,10] However, detailed retrospective analysis of the concomitant occurrence of intussusception and colic and *A. perfoliata* infections has failed to demonstrate any causal relationship between these conditions and tapeworm infections.[11] These parasites inhabit the region of the ileocecal junction and produce ulcerated lesions of the mucosa and submucosal inflammation. However, the

parasites are common, and possibly the association of tapeworm infections and clinical signs attributed to them are caused by chance alone. Detailed experimental investigations of these infections have not been conducted, and thus specific details on the pathogenesis and relevance of these lesions are lacking. However, an association between tapeworm infections and colic of ileocecal origin has been suggested in a case-control study of 231 horses.[12]

Until recently, cyathostomes (small strongyles) have not been considered of major importance, particularly as causative agents of colic. In this regard the field studies of Uhlinger are of particular importance.[13] In these controlled experiments, different anthelmintic treatment regimens were used to test their efficacy in reducing
the incidence of colic. The more efficacious treatment programs significantly reduced the incidence of colic by 90
2 to 13 times that seen in the same herds before implementation of the more efficacious treatment. Because of 91
the management programs used before the initiation of this study and the results of fecal cultures, one can assume that the primary parasites present in these horses were cyathostomes. These data strongly implicate a role for cyathostomes in a substantial proportion of colics observed under field conditions. The parasite or host factors involved in these colic cases are unknown.

Cyathostomes have been implicated in numerous case reports with seasonal diarrhea in adult horses, which is a condition called larval cyathostomiasis. These cases are characterized by a sudden onset of diarrhea during the late winter or spring. Mature horses usually are affected, and infections are often fatal. The condition is difficult to diagnose, and the only consistent signs are weight loss and diarrhea.[14] Large numbers of larval cyathostomes are found in the feces or in intestinal contents and within the mucosa of these horses. These symptoms are related to the synchronous emergence of fourth-stage larvae of these parasites from the mucosa. These larvae build to potentially large numbers within the mucosa because of the arrested development of infective larvae. The seasonality of the occurrence of this condition at present does not appear to vary in different climatic regions as does the analogous bovine condition of type II ostertagiasis. Specific parasite or host factors associated with the regulation of the hypobiotic state of the larvae or the inflammatory response initiated at parasite emergence have not been described.

In view of the paucity of specific mechanistic information on the pathophysiologic effects of equine gastrointestinal parasites, a synopsis of relevant information gathered from other model systems is warranted.[2,15] Parasitic organisms may induce changes in gastrointestinal function directly by mechanical disruption of tissues and cells or by the release of factors that directly alter cell function. Induction of the immune response serves as an anamnestic amplification system. The result of these changes is an alteration in function of the smooth muscle and epithelium of the bowel. A number of helminth parasites, including *P. equorum*, have been demonstrated to produce intestinal smooth muscle hyperplasia. Evidence suggests that this response may be induced by intestinal inflammation or stenosis associated with parasitism. Contractility of these muscles also has been demonstrated to be induced in a Schultz-Dale reaction by stimulation with parasite antigens. This response is mediated in rats by mast-cell–derived 5-hydroxytryptamine and in guinea pigs by histamine. A regulatory relationship of myenteric neurons to these antigen-induced changes also has been demonstrated in this model system. These latter experiments suggest that antigen-induced stimulation of smooth muscle contractility may be blocked correspondingly by γ-aminobutyric acid similarly stimulated by mast cell products. This complex system may be an adaptation by the host to maintain homeostasis in the face of continued antigenic stimulus. What is noteworthy is that strongyle-induced alterations in myoelectric activity of the equine small intestine and colon have been demonstrated in vivo.[16,17] In some of these experiments, dead *S. vulgaris* larvae evoked an alteration of the smooth muscle response in previously exposed ponies, suggesting a role for the immune response in the stimulation of the hyperactivity.[18]

A recent series of in vitro and in vivo experiments on the direct interaction of factors produced by the adult heartworm *Dirofilaria immitis* and arterial endothelium are exciting and noteworthy.[19] The results of these studies indicate that endothelial cell–mediated vasodilation is depressed in the presence of small (100 to 1000 molecular weight) parasite-derived pharmacologically active substances. Seasonal pathologic changes in infected arteries in dogs have been associated with the release of these substances by adult parasites. The nature of the factor or factors involved is unknown at this time. Production of similar factors in the mucosa or mucosal vasculature by nematodes could induce focal alteration in blood flow and other physiologic effects on smooth muscle. In general, these studies demonstrate the potential variety and complexity of metazoan-host interactions that have yet to be defined.

Many parasites and other infectious agents alter the structure of the intestinal epithelium, causing villous atrophy and crypt hyperplasia. Hypersensitivity responses are linked to functional changes in epithelium, such as decreases in epithelial brush border digested enzyme activity, decreased absorption, reduction in fluid absorption, and an increase in fluid secretion.[2] In vitro studies on the Cl^- secretion of isolated intestines from guinea pigs and rats infected with the nematode *Trichinella spiralis* have proved to correlate with in vivo fluid secretion.[15] In this system, antigenic stimulation induces an increase in Cl^- secretion similar to that induced by cholera toxin. The mechanism of this phenomenon in rats is mediated by antiparasite immunoglobulin E–mast cell release of at least two pharmacologically active substances that function in two phases. The immediate response depends on T cell–mediated mast cell hyperplasia, which is important in the release of 5-hydroxytryptamine and histamine. These factors act on enteric neurons to induce the immediate increases in Cl^- secretion from epithelial cells. The second phase is independent of mast cell hyperplasia and is mediated through 5-hydroxytryptamine and histamine–initiated increase in de novo mucosal synthesis of prostaglandin, which mediates a second phase of secretion. These in vitro phenomena can be blocked at various stages by 91
extrinsically supplied pharmacologic agents. The suggestion is that similar levels of control may be active in 92
vivo, mediating these effects and maintaining homeostasis in most cases. Although studies of this nature have not been conducted with equine tissues or parasites, similar mechanisms and activities likely occur.

* The authors acknowledge and appreciate the original contribution of Thomas R. Klei, whose work has been incorporated into this section.

2.3.1.2 RESPIRATORY SYSTEM

Several nematode parasites infect the equine lung. These include migrating stages of *P. equorum* and *Strongyloides* en route to the small intestine. Migrating stages of aberrant parasites, such as *Habronema* sp., *Draschia megastoma*, and *Strongylus* spp., which induce granulomatous foci in the lung parenchyma, and adults and larvae of the lungworm *Dictyocaulus arnfieldi*, which inhabit the bronchi, also occur. Host responses to two of these are noted.

P. equorum larval migrations in the lungs of yearling horses produce more severe clinical signs and inflammatory responses than in foals reared parasite-free. These infections in yearlings are accompanied by focal accumulations of lymphoid tissue, indicating an induction of an active local immune response. The reaction suggests that this is an age-related phenomenon.[8] However, more severe reactions likely could result from previous sensitization to *P. equorum* antigens. Increased responses of this nature have been described in the livers of pigs immunized with *Ascaris suum* antigens following challenge infections.

Dictyocaulus arnfieldi infections of donkeys rarely produce clinical signs, and these equidae have been suggested to be the natural host for this parasite. Infections of horses produce more severe and prolonged

bronchial inflammatory responses similar to *Dictyocaulus* sp. infection in other hosts. The mechanisms associated with this differential response have not been defined but are common in unadapted host-parasite associations. Possibly the more significant inflammatory reaction of the horse to these parasites is caused by the absence of down-regulatory mechanisms that are established in the more adapted natural host, the donkey.

2.3.1.3 SKIN

Reactions to the filarial nematode *Onchocerca cervicalis* illustrate variations seen in responses to chronic parasite infection. Focal, alopecic, depigmented, pruritic lesions often are seen in infected horses. Not all infected horses react to this infection, and the appearance of clinical signs is often seasonal. Detailed studies have not been conducted on the pathogenesis of these lesions in horses. However, similar conditions occur in human onchocerciasis,[20] and the host-parasite responses active in human beings likely are also present in the horse. Lesion development is associated with immune-mediated killing of microfilariae in the skin. Parasites appear to be killed in an antibody-dependent cell-mediated reaction. In this response, antimicrofilarial surface immunoglobulin G and E antibodies mediate adherence and degranulation of granulocytes, which are predominantly eosinophils. The major basic protein of eosinophils has been demonstrated in the tissues of patients with dermal lesions, and eosinophil toxic enzymes and proteins are responsible for many of the changes seen. The reason for the absence of these lesions in most horses is unclear. Human onchocerciasis and filariasis are spectral diseases in which regulation of immune responses has been associated with the lack of pathologic responses to the parasites.[21] Immune regulatory mechanisms associated with these infections include immune tolerance, anergy, induction of immune regulatory circuits involving suppressor T cells or macrophages, and most recently the potential shift in T helper cell subsets, which potentially alters the production of specific cytokines during different phases of the infections. The parasites themselves also may play a role in these regulatory responses. High-molecular-weight proteins and phosphorylcholine-containing proteins isolated from filariae have been demonstrated to suppress lymphoproliferation in vitro.[22] Although the activity of these proteins is yet to be demonstrated in vivo, chemotherapeutic elimination of circulating microfilaria from infected individuals restores previously suppressed parasite-specific lymphocyte responses. The presence of these types of parasite-associated immune regulatory events has yet to be studied critically in the horse. However, the seasonal variability in skin responses to the *Onchocerca* microfilariae by horses in some regions has been investigated. In this instance, the onset of ventral-midline dermatitis during the summer may be related to a seasonal fluctuation in microfilarial burdens of the skin, which also peak at this time.[23] Not only do total numbers increase, but also the microfilariae are found more commonly in the surface layers of the skin. Interestingly, this period of abundant microfilariae corresponds with the seasonal peak in numbers of the vector *Culicoides varripennis*. Although speculative, correlations in the peak availability of microfilariae and vectors may be an evolutionary adaptation by these parasites to maximize transmission and survival of this parasite species.

2.3.2 Protective Resistance

Resistance to infection may be innate or acquired. In some instances, innate resistance to equine parasites has been attributed to age, with older individuals being resistant. Most equine helminth parasites only develop in the horse, and conversely the horse exhibits an innate resistance to most nonequine parasites. Exceptions to this rule are parasites with a broader host range that occasionally infect horses, such as larvae of the tapeworm 92
Echinococcus granulosus and the liver fluke *Fasciola hepatica*. *Trichostrongylus axei*, a parasite of ruminants, 93
establishes readily in the equine stomach and only produces significant lesions when present in large numbers. In

some cases, parasites that develop in the horse induce more severe lesions and clinical signs than in their apparent normal host, as has been described for *D. arnfieldi*.

Age resistance to *P. equorum* and *S. vulgaris* has been described to occur in horses by comparing susceptibility of young and old ponies reared under parasite-free conditions. Apparently the reaction of the lung to migrating *P. equorum* larvae is more significant in mature horses and suggests that an immune response occurs in this site.[9,10] Initial reports on age-acquired resistance to *S. vulgaris* infection have not been substantiated by further experimentation, and these results remain equivocal.[24]

The occurrence of acquired resistance to equine parasites can be inferred from the observation that older, chronically exposed horses generally have lower burdens of parasites than do similarly exposed young horses. With these criteria, acquired resistance is apparent to infections with *Strongyloides, P. equorum, Strongylus* spp., and cyathostome species. Extensive experiments are limited, however, to those on *S. vulgaris*.

The level of resistance acquired in most cases is partial and of a concomitant type; that is, some stages of the parasite, such as arterial larvae of *S. vulgaris*, may reside within the horse in the face of an active acquired resistance against newly acquired infective stages. Resistance to infection with *S. westeri* adult parasites is inferred by the short duration of their life cycle within the small intestine and the failure of subsequent exposures to establish patent infections. Mares, however, remain infected with arrested third-stage larvae, which subsequent to foaling are transmitted to the foals in milk four days postpartum. Although not studied in horses, similar phenomena occur in swine strongyloidosis. In these infections, an apparent protective resistance against the migrating stage L_3 parasite occurs that is effective in preventing reestablishment of the intestinal infection but is ineffective against L_3 parasites, which are sequestered in the abdominal fat of the sow.[25] Similar epidemiologic phenomena occur in *S. westeri* infections of horses implying that similar immunologic mechanisms are also active.

Immunologic mechanisms associated with protective resistance are presented primarily as they relate to parasites that inhabit the lumen of the gastrointestinal tract and secondly as those that undergo extensive extraintestinal tissue migration.

2.3.2.1 GASTROINTESTINAL PARASITES

Immune responses directed toward gastrointestinal nematodes vary significantly among hosts and against different parasite species within a given host.[22] However, some generalities may be stated that may serve as a background for understanding these responses in the horse. A phenomenon termed *self-cure* has been described in sheep, in which the ingestion of significant numbers of infective larvae induces the expulsion of existing adult parasites. This expulsion is initiated by a species-specific immediate-type hypersensitivity response that may cause the nonspecific expulsion of other nematode species. Although this phenomenon has not been examined in the equine, experimental infections of naturally parasitized ponies with large numbers of *S. vulgaris* L_3 induced a dramatic decrease in preexisting strongyle fecal egg counts, suggesting that a self-cure–like reaction may occur under some conditions.

More typically, establishment of primary infections results at some time in spontaneous expulsions of these worms because of senility or, as demonstrated in laboratory animal model systems, active acquired immune responses. This phenomenon occurs experimentally in the absence of reinfection and is thus separate from the self-cure phenomenon. A confusing number of immune effectors have been identified with this phenomenon in various model systems, and likely some if not all are at some time active in the equine intestine. The

mechanisms involved are T cell dependent. Antibodies may be involved but are not sufficient in themselves to induce expulsion. T cell–mediated mastocytosis, eosinophilia, and goblet cell hyperplasia have been demonstrated to be related to expression of expulsion in some systems. These accessory cells are involved in the nonspecific efferent arm of this response. Mediators of inflammation, such as vasoactive amines, prostaglandins, and increased mucus production, have been linked to immune elimination of primary infections in some but not all model systems. A number of specific immunologic events likely initiate several nonspecific effector mechanisms, resulting in this expulsion. These mechanisms vary with the species of parasite involved. The elimination of adult *S. westeri* and *P. equorum* from maturing horses and the hypothetical seasonal turnover in *Strongylus* spp. and cyathostome species may be mediated by such responses.

In addition to immune responses that occur during tissue migrations, protective resistance to reinfection by gastrointestinal nematodes occurs at the surface of the epithelium. This reaction, termed *rapid expulsion* or *immune exclusion*, is separate from self-cure or immune expulsion of primary infection. Infective larvae are expelled from the intestine in a matter of hours. Again mechanisms of expulsion described vary between parasite and host species. However, anaphylactic reactions and mucus entrapment have been observed. Some experiments using the *Trichinella spiralis*–rat system suggest that alterations in the epithelial cells in immune animals are involved directly in the exclusion of these parasites. Although immune-mediated damage of intestinal helminths such as decreased fecundity, reduced size, and morphologic alterations have been noted, infective larvae expelled by rapid expulsion mechanisms remain viable and undamaged. One may speculate that reactions of this nature are responsible in part for resistance to reinfection of equines with cyathostomes. 93 94

2.3.2.2

TISSUE-MIGRATING PARASITES

A number of intestinal helminths migrate through extraintestinal tissues as part of their life cycle. These include parasites such as *P. equorum, Strongyloides westeri*, and *Strongylus* spp., all of which stimulate an acquired immune response in the horse. During this migration, larvae are vulnerable to attack by immune effectors that may encapsulate them in an immune-mediated inflammatory response, disrupt their migrations by interfering with important metabolic or invasive processes, or inhibit molting from the L_3 to L_4 stages. The most studied phenomenon in this regard is antibody-mediated adherence of inflammatory cells, which may result in killing of the larvae. This phenomenon has been demonstrated to involve many cell types and immunoglobulin isotypes in different host-parasite systems. In vitro studies of this nature have been conducted using *S. vulgaris* third-stage larvae and equine immune effectors in the author's laboratory. In these experiments, an antibody-dependent adherence of cells was demonstrated and shown to be parasite species-specific. In vitro killing was mediated by eosinophils and not by neutrophils or monocytes. Activated eosinophils were necessary to mediate this response, and *S. vulgaris* infections have been demonstrated to activate eosinophils and neutrophils in vivo.[26] Although eosinophils are not known with certainty to be essential in this protective immune response, an anamnestic eosinophilia is characteristic in immune ponies but not nonimmune ponies following experimental *S. vulgaris* challenge. Because of its prominence and compelling in vitro and correlative in vivo data, the eosinophil has been considered to be a major effector in immune-mediated helminth killing. However, recent studies in murine parasite model systems in which eosinophilia was blocked by anti–interleukin-5 treatment suggest that this type of cell is not essential for protective resistance in some systems.[27] Possibly, in vivo a number of cells function as effectors and may overcome the absence of sufficient eosinophils under some circumstances. Antibody reactivity with parasite-secreted enzymes and molting fluids, factors important in parasite homeostasis, have been demonstrated in vitro; and similar reactions may be important in vivo.

T cell responses are essential for the induction of protective resistance to tissue-migrating helminths in most systems studied, including the experimental *S. vulgaris* pony model. This dependency likely is caused by the T cell dependency of the antibody response and by the mediation of secondary effector cell responses. Antigenic substances secreted or excreted by migrating nematodes likely are important in the induction of these responses. A combination of immune responses elicited by a combination of specific parasite antigens, including surface antigens and secreted or excreted products, probably is necessary to induce an immune response sufficient to provide protective resistance.

2.3.3 Parasite Evasion of Immune Effectors

Some parasites that live for long periods within a host modulate the host response in a specific and a nonspecific fashion, as described previously for filarial infections. What is inferred is that this modulation inhibits immune responses associated with protective resistance. In addition, blocking antibodies that inhibit antibody-dependent eosinophil killing of schistosome larvae have been described in rodent models and in sera from infected patients. The role of these types of antibodies in other infections is unclear.

A number of parasite-driven mechanisms have been described that promote parasite survival within hosts possessing strong immune responses directed toward their antigenic components.[28] Others mask themselves to avoid recognition or directly inactivate immune effectors. Host molecules shown to be attached to the surface of parasites include glycolipids of blood group antigens, glycoproteins, serum proteins, and class I and II major histocompatibility complex molecules. In some instances, hostlike molecules have been demonstrated to be encoded in parasitic helminth genomes and expressed on their surfaces. This phenomenon, termed *molecular mimicry*, has been postulated to be a mechanism evolved by the parasite to mask itself from the host immune surveillance systems.

Some parasites, notably tapeworm larvae, produce factors that activate complement and may produce a state of localized complement depletion in vivo. Other factors from tapeworm larvae disrupt the coagulation cascade and others have antiinflammatory activity.[29] Filarial nematodes synthesize prostaglandins from host arachidonic acid and release these in vitro and potentially in vivo.[30] These molecules may be responsible for local modulation of inflammatory cell function and may play a role in the survival of parasites.

These types of mechanisms have been identified in most host-parasite systems examined and are likely active in the horse. These intriguing phenomena, however, have yet to be investigated in equine parasite infections. 94

95

2.3.4 Mechanisms of Anthelminthic Resistance

Three main target sites for anthelmintic activity against helminth infections are ion channels, microtubules, and energy-requiring transporters.[31] The tetrahydropyrimidines (pyrantal), imidazathiazoles (levamisole), macrocytic lactones (ivermectin and moxidectin), and piperazines target some type of ion channel. Microtubules are the main targets of benzimidazoles.[32] Salicylanilides and chlorinated sulfonamides target energy-requiring processes of the helminths.

Like bacterial resistance to antimicrobials, resistance to anthelmintics is associated with a genetic modification that transforms a susceptible population of parasites into a resistant one.[31] Intensive use and inappropriate or ineffective dosing of therapeutics contributes to development of resistance. Presumably, treatment eventually eliminates susceptible individuals, allowing for accumulation of resistance genes within the remaining

population. Rather than passing genetically encoded material by transmissible elements, resistance is passed through successive generations of allelic inheritance.

Benzimidazoles are a useful class of anthelmintic because of their specificity for nonmammalian microtubules.[31] Interference in microtubule function disrupts the transport of vesicles that contain gut secretions to the outer surface of the parasite.[33] Resistance is thought to be due to selection of certain β-tubule allelic isotypes that are associated with the loss of high-affinity binding sites on the β–tubulin protein.[34] Specifically, the loss of the β-tubulin type 2 isotype allele from the population and the addition of a point mutation of the type 1 isotype results in attainment of high-level resistance in that population.[31,34]

Attainment of resistance to avermectins is complex and a major problem. Eventual resistance to milbemycins does occur. This phenomenon has been studied most extensively in *Haemonchus contortus* infections and *Caenorhabditis elegans*.[35] Macrocyclic lactones induce a flaccid paralysis that is mediated by interfering with the action of the glutamate-gated chloride channel. Acting as an agonist of glutamate, these anthelmintics prolong the opening of the channel. Three mutations of the genes encoding the glutamate-gated chloride channel are associated with high-evel resistance, and one to two changes result in some resistance.[36,37] Genetic changes in another set of nematode molecules, the P-glycoproteins also may be important in attainment of resistance.[31]

Pyrantel compounds are essentially acetylcholine agonists.[31] Spastic paralysis results from binding of the compound to the nicotinic acetylcholine receptor. Populations of worms appear to be heterogeneous in development of a spastic response to acetylcholine agonists. Resistance appears to occur from a shift to a homogenous population that is insensitive to the effect on the acetylcholine receptor.[38] Most of the testing has been performed with levamisole, but it appears that less sensitive receptor subtypes are also responsible for resistance to other nicotinic agents including pyrantel.[31]

Concern for the development of resistance in equine gastrointestinal parasites primarily centers on the development of resistance in cyathostomes.[32,39–45] Cyathostome resistance is a common finding for fenbendazole.[46] Fenbendazole resistance is apparent on 79% to 90% of farms tested in studies that use fecal egg counts as an indication of effectiveness of anthelmintic therapy. Even when sensitive, fecal egg counts are suppressed for less than 2 to 3 weeks. This resistance usually involves multiple species of small strongyles. Resistance to pyrantel is increasing. Efficacy has been reduced to as low as 60% effectiveness. Up to 30% of farms tested have demonstrated resistance to pyrantel. Dual resistance to fenbendazole and pyrantel has been demonstrated. Ivermectin resistance has not been reported for cyathostomes. Ivermectin, although still efficacious, suppresses egg counts for considerably less time than moxidectin.

2.4 2.4—Rickettsial Diseases

Yasuko Rikihisa

Potomac horse fever (PHF) and equine ehrlichiosis are two rickettsial diseases known to affect horses. Diagnosis of these diseases requires an awareness of the typical pattern of clinical signs, hematologic values, seasonal pattern, and prevalence of the disease in the area. Because of the frequent international and domestic transport of horses, knowledge of the previous location of the horse also may aid in diagnosis. PHF is transmitted by oral ingestion of trematodes present in aquatic insects. Equine ehrlichiosis is transmitted by ticks. For both diseases, serologic testing by indirect fluorescent antibody (IFA) test is the primary method of laboratory diagnosis. Polymerase chain reaction (PCR) methods are also useful for detection of both infections. When the diseases are diagnosed correctly at acute stages of infection and are treated properly, the prognosis for horses with equine ehrlichiosis is excellent and that for horses with PHF is excellent to good in uncomplicated cases.

96

97

2.4.1 Potomac Horse Fever

2.4.1.1 GEOGRAPHIC DISTRIBUTION

PHF (equine monocytic ehrlichiosis, equine ehrlichial colitis, or acute equine diarrhea syndrome), a rickettsial disease of equidae, was recognized originally in 1979 along the Potomac River in Montgomery County, Maryland.[1] The disease also may have existed in northern California since the 1970s.[2] PHF is now known to occur serologically in 43 of the United States, two provinces (Ontario and Saskatchewan) in Canada, France, Italy, Venezuela, India, and Australia. However, confirmation by isolation of the causative agent has been made only in the United States. The disease is caused by a rickettsial organism currently designated *Neorickettsia risticii* (formerly *Ehrlichia risticii*[3,4]), which is serologically distinguishable from other pathogenic species infecting horses.

2.4.1.2 CAUSE

In 1983, PHF was shown to be transmitted between horses by whole blood transfusion.[1] This finding made laboratory experiments under controlled conditions possible. In 1984, serologic cross-reactivity of sera of infected horses with *Neorickettsia sennetsu* (formerly *Ehrlichia sennetsu*), a human Sennetsu fever agent in Japan, was noted.[5] In the same year, the presence of ehrlichial organisms in macrophages and glandular epithelial cells of the intestinal wall of affected horses was demonstrated by transmission electron microscopy.[6] The causative agent was isolated independently in different laboratories using human histiocytic lymphoma

U-937 cells,[7,8] canine primary monocytes,[5] and murine P388D$_1$ cells.[9,10] The agent was confirmed to reproduce disease in horses and was reisolated from horses with experimentally induced disease.[5,8,9]

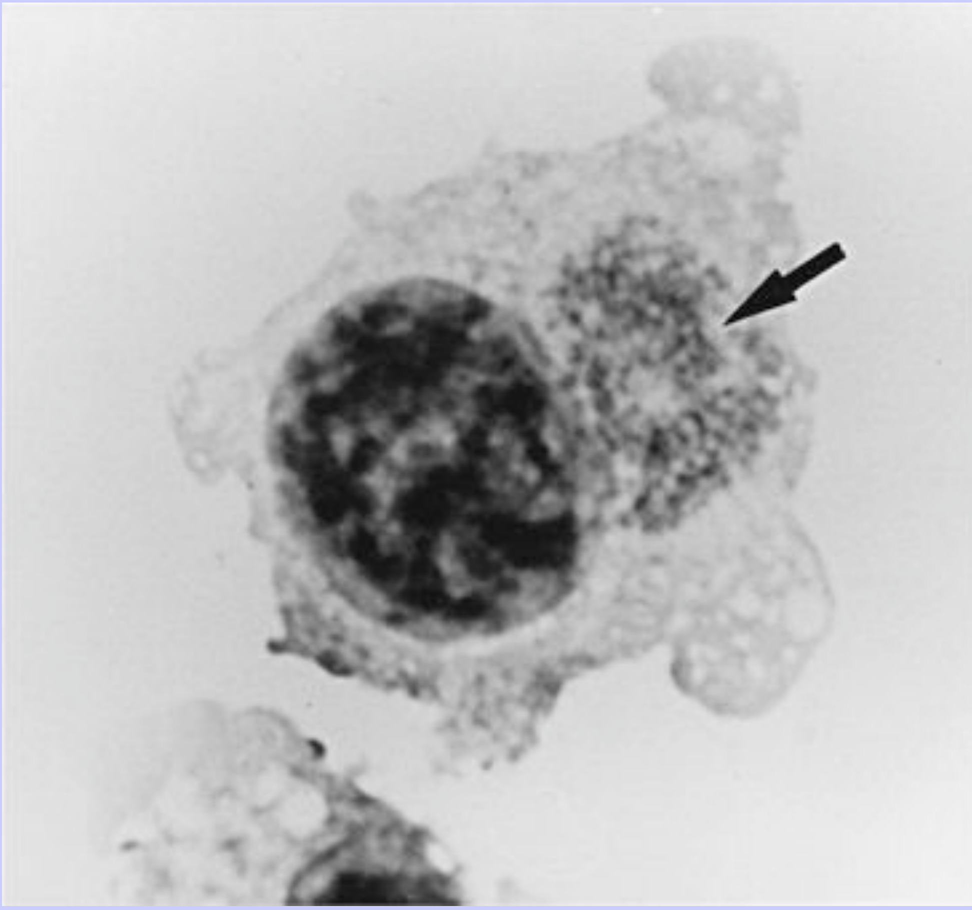
N. risticii currently is classified among three *Neorickettsia* species.[4] The genus *Neorickettsia* belongs to the family Anaplasmataceae along with the genera *Ehrlichia* and *Anaplasma*, which are obligatory intracellular bacteria with a tropism for hematopoietic cells, and the genus *Wolbachia*, which consists of intracellular symbionts of invertebrates. All these microorganisms belong to the α subdivision of the proteobacteria. None of the family Anaplasmataceae has been cultured outside of eukaryotic cells or in yolk sacs.[11] Success in culturing *N. risticii* in macrophage cell lines made possible the obtaining of the quantities of organisms needed for basic research at the molecular and cellular levels and for development of serologic tests and vaccines.

The family Anaplasmataceae is included in the order Rickettsiales along with the family Rickettsiaceae.[4] 16S ribosomal RNA gene sequence comparison currently is considered to be the most reliable method to determine phylogenetic relatedness among bacteria. Studies have shown relatedness (81.7%) in the sequences of the 16S rRNA gene in *N. risticii* and *Rickettsia prowazekii*, which is the causative agent of epidemic typhus, a well-known rickettsial disease responsible for the deaths of millions of persons during wartime and natural disasters. The percentage of 16S rRNA gene sequence homology between *N. risticii* and *N. sennetsu* is 98.9%, and the next related bacterium is *N. helminthoeca* (94.8% 16S rRNA gene sequence homology).[12] *N. helminthoeca* is the causative agent of salmon poisoning disease of the dog. *N. helminthoeca* is transmitted by trematodes, is antigenically cross-reactive with *N. risticii*, and biologically and morphologically resembles *N. risticii*.[13] Furthermore, the 16S rRNA gene of the trematode *Stellantchasmus falcatus* (SF agent) is 99.1% homologous to that of *N. risticii*.[14] Within 11 *N. risticii* strains, a maximum of 10 nucleotides are different (0.7% divergence).[15]

N. risticii is genetically divergent from *Anaplasma phagocytophilum* (formerly *Ehrlichia equi*)—which causes equine ehrlichiosis, tick-borne fever, and human granulocytic ehrlichiosis (HGE)—and *E. canis*, which is the type species of the genus *Ehrlichia*, by 16S rRNA gene sequence comparison, homology being 83.3% and 82.4%, respectively.[16]

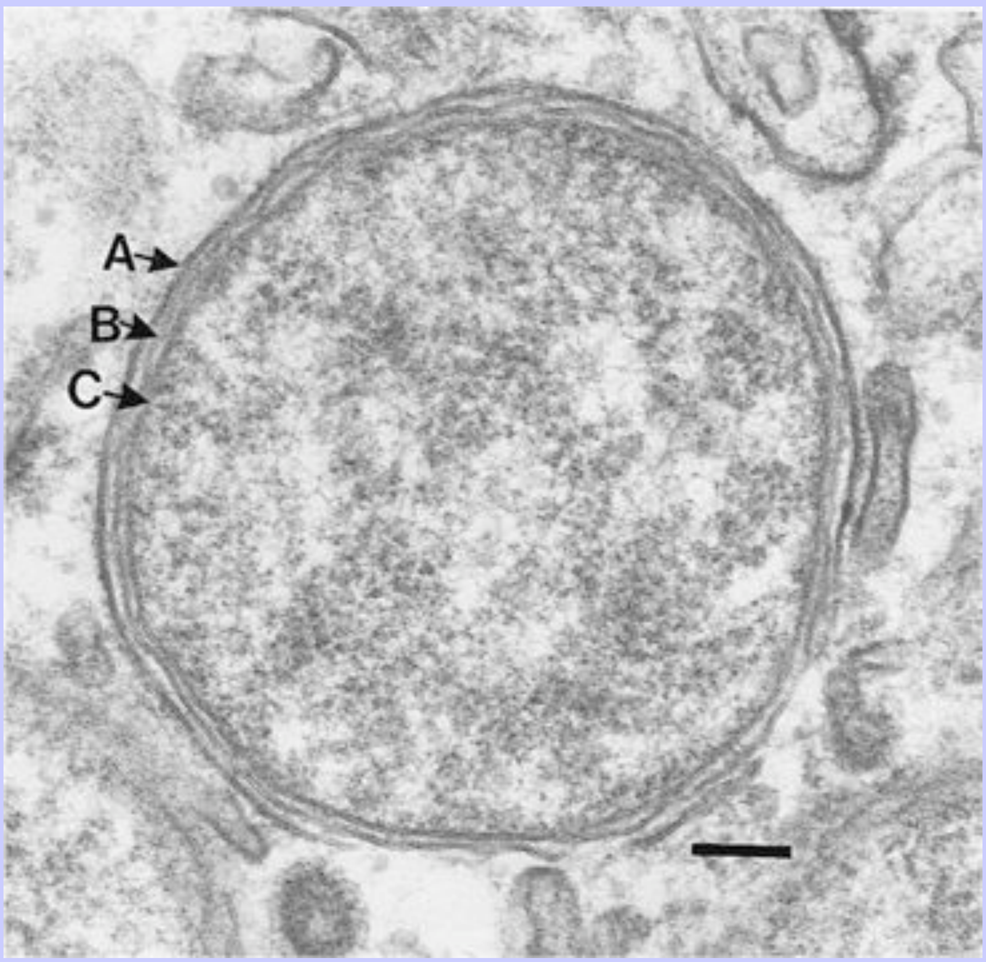
N. risticii is a tiny gram-negative coccus and stains dark blue to purple with Romanowsky's stain (Figure 2.4-1). *N. risticii* tends to occupy one side of the cytoplasm rather than being symmetrically or evenly distributed. *N. risticii* generally is round but sometimes is pleomorphic and may be elongated, especially in tissue culture. The organism divides by binary fission and is found in membrane-lined vacuoles within the cytoplasm of infected eukaryotic host cells, primarily macrophages and glandular epithelial cells in the intestine of the horse. *N. risticii* occurs in at least two different forms: multiple dark, small organisms (0.2 to 0.4 μm) enveloped by the host membrane (called morulae) and relatively light, large forms (0.8 to 1.5 μm) individually tightly wrapped with host membrane.[17,18] Morulae appear to interchange with individually enveloped forms, because an intermediate stage appearing as moderately dense ehrlichial cells tightly 97
enveloped with the host membrane that is continuous with the membrane surrounding a morula, has been seen. 98
[19] *N. risticii* in T-84, P388D$_1$, and U-937 cells, in primary equine monocyte culture, and in infected equine tissues is seen primarily in individual forms, especially in intestinal epithelial cells.[19,20] However, several recent *N. risticii* isolates make inclusions as large and as tightly packed as *E. canis* inclusions.[21,22] Vacuoles containing *N. risticii* do not fuse with lysosomes. The inhibition of lysosomal fusion is not a generalized process but rather is restricted to vesicles that contain *N. risticii*.[23]

Figure 2.4-1 *Neorickettsia risticii* in the cytoplasm of P388D$_1$ cells. Organisms are stained dark purple of Diff-Quik staining *(arrow)*. (×4000.)



Transmission electron microscopy reveals that *N. risticii* has distinct ribosomes and DNA strands.[17–19] Clumps of ribosomes are distributed homogenously in the cytoplasm rather than being marginated beneath the cytoplasmic membrane. Compared with those of the rickettsiae or ordinary bacteria, the DNA and ribosomes in *N. risticii* are packed more loosely in the cytoplasm except for the small, dense form. Thus the electron density of ehrlichial organisms is similar to that of the host cell cytoplasmic background, and this low contrast makes finding *N. risticii* in infected tissue difficult at low magnification under the electron microscope. *N. risticii* is surrounded by thin, bileaflet outer and inner membranes (Figure 2.4-2). Unlike the rickettsiae, ehrlichial organisms show no thickening of either leaflet of the outer membrane.[18,19] Morphologically, *N. risticii* does not appear to contain significant amounts of peptidoglycan.[19] Peptidoglycan is counterproductive when considering the intracellular life of *N. risticii* because the organism requires the provision of an effective diffusion rather than mechanical protection by peptidoglycan.

Figure 2.4-2 Transmission electron micrograph of *Neorickettsia risticii* in the cytoplasm of a macrophage in the large colon of a horse. *N. risticii* is enveloped tightly by the host membrane *(A)* and has its own outer *(B)* and inner *(C)* membranes. (×105,000.) Bar = 0.1 μm. (Reproduced with permission of Yasuko R: Ultrastructure of rickettsiae with special emphasis on ehrlichiae. In Williams JE, Kakoma I, editors: *Ehrlichiosis*, Dordrecht, The Netherlands, 1990, Kluwer Academic Press. Reprinted by permission of Kluwer Academic Publishers.)



No plasmid or phage has been detected by agarose gel electrophoresis of DNA fractions from *N. risticii* cultured in vitro. Lipopolysaccharide is not readily detectable by the conventional extraction method or silver staining.[11] Recent analysis of *N. sennetsu* and *A. phagocytophilum Ehrlichia chaffeensis* genome sequencing data confirms the absence of genes for lipid A biosynthesis and most of genes for peptidoglycan biosynthesis.

[23a] No endospore-like structure has been reported, although minicell-like structures resulting from uneven binary fission and apparent outer membrane vesicles of various sizes have been seen in *N. risticii*.[18]

N. risticii appears to perform aerobic and asaccharolytic catabolism. The metabolic activities of *N. risticii* have been investigated. *N. risticii* can use glutamine and glutamate and generate adenosine triphosphate as rickettsiae do.[10,24] The preference of glutamine over glutamate is likely because glutamine penetrates phagosomes better than glutamate. *N. risticii* cannot use glucose-6-phosphate or glucose[10] and is similar to the genus *Rickettsia*, but the rate of adenosine triphosphate synthesis is much lower than in *Rickettsia typhi*.[24] The greatest metabolic activity of *N. risticii* is observed at a pH of 7.2 to 8.0 and declines drastically at a pH below 98
7.[10] This finding suggests that *N. risticii* can prevent acidification and lysosomal fusion of the vacuole where 99
it resides.

2.4.1.3 EPIZOOTIOLOGY

No sex, age, or breed predilection exists for equine infections based on serologic testing of horses in Ohio.[25] The disease occurs along big rivers and their tributaries mainly during the summer and is most common from June through September. DNA from *N. risticii* has been detected in virgulate cercariae in freshwater operculate snails (Pleuroceridae: *Juga yrekaensis*) from northern California,[26,27] in virgulate xiphidiocercariae isolated from snails (Pleuroceridae: *Elimia livescens*) in central Ohio,[28] and from snails (Pleuroceridae: *Elimia virginica*) in central Pennsylvania.[29] This type of trematode is known to become metacercaria in aquatic insects, and *N. risticii* DNA has been detected in mesocercaria and metacercaria in various aquatic larval and adult insects such as mayflies and caddisflies in northern California[30] and in central Pennsylvania.[29] One horse fed adult caddisflies in northern California[31] and two horses fed adult caddisflies or a mixture of adult caddisflies and mayflies in central Pennsylvania developed PHF.[29] 16S rRNA gene sequences and 51-kd antigen amino acid sequences obtained from culture isolates from horses, horse blood, and caddisflies were identical, proving oral transmission and establishment of stable infection of *N. risticii* in the horse as the cause of PHF in Pennsylvania.[29] Ingestion of the larval stage of aquatic insects or cercariae in the water did not transmit *N. risticii*.[31] Blood-sucking arthropods such as *Dermacentor variabilis*, black flies, eye gnats, biting midges, and mosquitoes have been found to be negative for *N. risticii* transmission.[32]

Experimental injection of cell-cultured *N. risticii* or infected horse blood and reisolation of the organism have revealed that dogs, cats, mice, and nonhuman primates can be infected, although only mice and cats developed significant clinical signs.[33–36] PHF may have zoonotic potential, because *N. risticii* can cause mild clinical signs in primates.[36] Seroepizootiologic studies showed that cats, dogs, foxes, pigs, and goats in an endemic area of Maryland develop antibodies to *N. risticii*.[37] The reservoir potential of these animals is currently unknown. Dogs demonstrating symptoms of canine ehrlichiosis were seropositive to *N. risticii* (but not *E. canis*), and an agent identical to the 16S rRNA *N. risticii* was isolated from the dogs in this report.[38] However, the potential for this canine isolate to infect horses and cause PHF is undetermined.

Owners and veterinarians should be aware of the sporadic nature of PHF. On some farms and racetracks, the disease recurs several summers in a row. Alternatively, the disease may appear suddenly in isolated areas where no previous PHF cases have been reported. Usually, if clinical cases are confirmed serologically on a farm, racetrack, or horseshow, several additional seropositive horses show no clinical signs. Of horses at two racetracks in Ohio, 13% (138 of 840) to 20% (116 of 574) were exposed to *N. risticii*, according to the results

of a serosurvey conducted in the summer of 1986.[25] Of seropositive horses, 80% to 90% did not show clinical signs of infection.

2.4.1.4 PATHOGENESIS AND IMMUNE RESPONSES

2.4.1.4.1 Establishment of Infection

N. risticii can establish infection in mice and horses with or without causing apparent clinical illness. In a murine model of PHF, disease is apparently dose dependent.[39] Only at higher dosages can the organism cause disease and pathologic changes. In mice, susceptibility varies among strains.[40]

N. risticii can be reisolated from the peripheral blood monocytes of horses starting from day 6 to day 11 after ingestion of adult aquatic insects harboring *N. risticii*,[29] and ehrlichemia persists 1 to 2 weeks after spontaneous resolution of clinical signs.[29,41,42] *N. risticii* may persist much longer in the intestinal walls of clinically recovered horses, for the homogenate of intestinal tissues recovered from two ponies at 2 months after infection contained *N. risticii* antigens.[43] Furthermore, in a pregnant mare-fetus system, *N. risticii* infection persists up to 4 months, for *N. risticii* was isolated from the spleen, bone marrow, and mesenteric and colonic lymph nodes of a 7-month-old fetus of a mare that was infected experimentally during the third month of gestation.[44]

2.4.1.4.2 Mechanism of Diarrhea

N. risticii infects blood monocytes and has a predilection for the intestinal wall, especially that of the large colon where it infects tissue macrophages,[6,17] intestinal glandular (crypt) epithelial cells, and mast cells.[16,17] *N. risticii*– infected cells are shed into the intestinal lumen as detected by electron microscopy[18] and by PCR of fecal specimens.[31,42] Watery diarrhea is caused by a reduction in electrolyte transport (Na^+, Cl^-); thus a lack of water resorption occurs, mainly in the large and small colons.[45] Infected intestinal epithelial cells lose microvilli,[20,45] which may contribute to the reduced electrolyte transport and water resorption. An increase in intracellular cyclic adenosine monophosphate is found in infected mouse macrophages and infected mouse and horse intestinal tissues.[45–47] This change in cyclic adenosine monophosphate content also may contribute to the reduced lumenal absorption of Na^+ and Cl^- in the colon and thus to the lack of water absorption and diarrhea.

2.4.1.4.3 Cellular Damage and Cytokines

In contrast to cells infected with virulent strains of the genus *Rickettsia*, host cells infected with *N. risticii*
show little cytolysis in vivo or in vitro until the cytoplasm is filled completely with infecting organisms and 99
cells burst. Ehrlichial release appears to occur not only by cell lysis but also through exocytosis by fusion of 100
the inclusion membrane with the plasma membrane. In the case of intestinal epithelial cells, which make a monolayer tightly connected by circumferential zones of intercellular junctions, ehrlichial organisms appear to be transmitted between adjacent cells in vitro by a coupled exocytosis in one cell and endocytosis in an adjacent cell.[20]

Unlike ordinary gram-negative bacteria, *N. risticii* does not activate macrophages fully in vitro. *N. risticii* induces only low levels of tumor necrosis factor α and prostaglandin E_2 production in macrophages. In contrast, infected macrophages produce large amounts of interleukin-1, and this may be related to the pathogenesis of the disease.[46] This difference may be caused by a lack of lipopolysaccharides in *N. risticii*. *N. risticii* in general does not induce a severe inflammatory reaction in equine tissues.[18,45]

2.4.1.4.4 Mechanism of Infection of Macrophages

Because *N. risticii* is an obligatory intracellular bacterium, the organism must bind to the proper receptor to induce internalization and to maintain an intracellular environment adequate for survival and proliferation. In vitro, professional phagocytes (monocytes and macrophages) of host animal species have no intrinsic resistance to infection with *N. risticii*. In addition, intestinal epithelial cells and mast cells, which are normally not phagocytic, are induced to take up *N. risticii. N. risticii* binds to equine macrophages but not polymorphonuclear leukocytes. *N. risticii* entry into $P388D_1$ cells is blocked by monodansylcadaverine, an inhibitor of transglutaminase that inhibits receptor-mediated endocytosis, suggesting entry in this fashion.[48] Ehrlichial internalization, proliferation, and intercellular spreading, but not binding, depended highly on the host transglutaminase and microtubule system,[48,49] as well as on calcium-calmodulin[50] and protein tyrosine kinase.[51]

N. risticii can be taken up readily by equine polymorphonuclear leukocytes but is destroyed rapidly in those cells.[48] Polyclonal equine antiserum to *N. risticii* does not inhibit binding or internalization of *N. risticii* to $P388D_1$ macrophages, but internalized antibody-coated *N. risticii* fails to survive.[52] Because the antigen-binding fragment of the equine anti–*N. risticii* immunoglobulin G (IgG) blocks the binding of *N. risticii* to $P388D_1$ macrophages, antibody-coated *N. risticii* most likely enters macrophages via the Fc receptor. The mechanisms of destruction of antibody-coated *N. risticii* in macrophages are presently unknown.

2.4.1.4.5 Immune Response

Recovered horses have been reported to be resistant to development of clinical disease on rechallenge for at least 20 months.[53] Humoral and cell-mediated immune responses appear to have significant roles in this protection. *N. risticii* induces a specific antibody response in the natural host or in experimental animals, regardless of the presence of clinical signs. The presence of the antibody, however, does not always correlate with clearance of ehrlichial organisms and presence of protective immunity. An IgM response occurs a few days after the initial infection and lasts for less than 2 months. A challenge injection did not elicit an IgM response. Several days after *N. risticii* infection of the horse, tests for IgG antibody became significantly positive.[54]

Development of neutralizing antibodies in infected horses also was demonstrated using a cell culture system and a murine model for PHF.[41] Three mechanisms of antibody neutralization have been shown. In the first mechanism, antibody blocks ehrlichial binding to its specific receptor, instead making it bind through the Fc receptor. In the second mechanism, the antibody directly inhibits ehrlichial metabolism as demonstrated by reduced $^{14}C\text{-}CO_2$ production from ^{14}C-L-glutamine in host cell–free *N. risticii* in the presence of the antibody.[52] The third mechanism is antibody-dependent cell-mediated cytotoxicity. Macrophages infected with *N. risticii* present ehrlichial antigens on their surface similar to virus-infected cells and are lysed when

incubated with antiehrlichial antibody and normal equine peripheral blood monocytes.[55] Five to seven major antigens were exposed on the surface.[56] These antigens are considered to be the target in antibody-mediated neutralization.

Although mouse resident peritoneal macrophages fail to generate superoxide on interaction with *N. risticii*, peritoneal macrophages from mice previously inoculated with *N. risticii* and further sensitized with *N. risticii* antigen inhibit *N. risticii* in vitro by generating superoxide.[57,58] Interferon-γ has the ability to activate uninfected and infected macrophages and transform them into effector cells. The ehrlichiacidal mechanism exhibited by interferon-γ was investigated using murine peritoneal macrophages. *N. risticii* was highly sensitive to nitric oxide, which was generated by macrophage cytoplasmic nitric oxide synthase induced by interferon-γ.[59] Spleen cells from recovered mice at 28 days after inoculation with *N. risticii* proliferated in response to *N. risticii* antigen.[60] Activities of T cells that generate interferon-γ are, however, severely depressed in infected mice in a dose-related manner.[39] One cause for depressed T cell response was found in macrophages. Class II histocompatibility antigen induction on the surface of *N. risticii*–infected macrophages (antigen-presenting cells) is suppressed in vitro,[61] suggesting inhibition of antigen-specific T cell activation in *N. risticii* infection. Thus an understanding of the immunodepression 100
mechanism and identification of T cell stimulating and ehrlichial antigens that induce neutralization are 101
keys toward developing an improved, more effective vaccine for PHF.

2.4.1.5 CLINICAL FINDINGS

The incubation period for *N. risticii* infection is approximately 1 to 3 weeks. Clinical signs are an acute onset of fever up to 107° F, depression, anorexia, decreased borborygmi in all abdominal quadrants, subcutaneous edema of the legs and ventral abdomen, dehydration, and diarrhea. Laminitis and severe abdominal pain occur in 15% to 25% and 5% to 10% of cases, respectively, which are the major reasons for euthanasia.[62] Laminitis may progress, despite resolution of other clinical signs. Diarrhea may be mild to severe "pipestream" and occurs in 10% to 30% of cases. In some horses diarrhea may be transient; in others cases diarrhea persists for several days; and still other horses may have no diarrhea. Owners and veterinarians should be aware of the variable nature of clinical signs. Case fatality rates vary from 5% to 30%. Transplacental transmission of *N. risticii* is reported, and the organism may induce abortion or resorption of the fetus or produce maladjusted foals, which require extensive neonatal care.[44,63–65] Recurrence of diarrhea and on and off prolonged illness in antibiotic-treated horses has been observed.[66] Leukopenia (white blood cell count <5000/μL) with a left shift and rebound leukocytosis (white blood cell count >14,000/μL) are prominent hematologic changes. Anemia, changes in plasma protein concentration, increased packed cell volume, and thrombocytopenia also may be observed.[67]

2.4.1.6 DIAGNOSIS

In contrast with *A. phagocytophilum* infection, visual observation of blood smears of suspected horses after Romanowsky staining is useless for diagnosis of *N. risticii* infection, because only a few blood monocytes are infected with a few organisms even at the acute stage of infection.

2.4.1.6.1

Serologic Diagnosis

All ehrlichial agents induce specific humoral immune responses that are the basis for serologic diagnosis of ehrlichial diseases. However, because serologic response occurs in every animal exposed to *N. risticii*, regardless of whether infection is established or disease is present, serologic testing alone, with no supporting information, provides limited information for the diagnosis of disease. Serologic diagnosis of ehrlichial infections is performed primarily by IFA.[54,68] The cutoff titer for positive serologic result may vary with the laboratory. In the author's laboratory, IgG IFA titers of 20 or higher represent a positive serologic result. For serologic testing for *N. risticii* infection, the higher the titer is, the greater the correlation is with PHF clinical disease. The chance of healthy horses having a titer of 40 or less is similar to that of ill horses (early and late stages, and low levels of infection with *N. risticii* or possible cross-reaction with other microorganisms). Thus at a titer of 40 or less, although the horse is seropositive, the current disease is not likely to be caused by *N. risticii*. The chance of having a titer of 80 or more and 640 or less is approximately 4 times higher in ill horses than in healthy horses, and the chance of having titers higher than 1280 is 12 to 26 times higher in ill horses.[25] In addition, all experimentally infected horses had an IFA titer of 80 or higher at the onset of clinical disease.

N. risticii has been adapted to grow in a continuous murine monocyte-macrophage cell line and other cell lines; thus antigen slides are easy to prepare.[54,69] IFA testing may produce false-positive results with equine sera when they bind nonspecifically to infected cells. Several means of solving this problem are these: First, *N. risticii* organisms should be seen clearly in the cytoplasm of the host cells by IFA staining at magnification of 1000 times. If staining is blurred, morphologically different from positive control staining or Giemsa-stained infected cells or if extracellular objects are stained, the sample should not be judged positive. Second, positive and negative control equine sera must be tested to ensure the quality of the entire IFA procedure each time, including the quality of the antigen slides used and fluorescein isothiocyanate anti-horse IgG. Third, to reduce nonspecific binding, the author's laboratory uses 0.02% Tween-20 in the phosphate buffered saline washes. Usually serial dilution of the serum takes care of the problem of nonspecific binding if the titer of the sera is sufficiently high. If none of these procedures work, the author preabsorbs the equine sera with uninfected macrophages cultured and prepared under the same condition as the *N. risticii*–infected macrophage antigen. Western immunoblot analysis has been developed and is useful in distinguishing sera that have a nonspecific IFA reactivity or react by IFA to cross-reacting antigens.[70,71]

An enzyme-linked immunosorbent assay (ELISA) has been developed using purified *N. risticii* as the antigen.[54] The IgM titer rises earlier during the course of infection than the IgG titer. A rise in IgM titer occurs only at the time of initial infection, and the titer becomes negative in 1 to 2 months.[55] Thus an IgM ELISA is not useful for detecting chronic or multiple infections but is useful for early diagnosis of a primary infection of nonvaccinated horses. Several other serologic tests such as latex agglutination[72] and monoclonal antibody–based competitive ELISA have been reported.[73] However, to date a rapid and reliable field serodiagnostic test is not yet available.

No significant serologic cross-reactivity occurs between the family Anaplasmataceae and the families 101
Rickettsiaceae and Chlamydiaceae by the IFA test.[3,5,11] *N. risticii* has only minor heat-sensitive antigenic 102
determinants, unlike the genus *Rickettsia*. By Western blot (immunoblot) analysis, however, cross-reactivity of 55-kd heat-shock protein 60 homolog with those of other *Neorickettsia, Anaplasma*, and *Ehrlichia* spp. and *Rickettsia* spp. is detected.[74,75]

Several ehrlichial species antigenically cross-react within the genus when tested by IFA or Western blot analysis.[13] Within the genus *Neoricketsia, N. risticii* and *N. sennetsu* share the strongest common antigens. *N. sennetsu* is nonpathogenic to horses but it protects them from *N. risticii* infection.[71]

Immunologic cross-reactivity among members of the genus *Neorickettsia* does not create a serious problem in serologic diagnosis because of the host animal specificity of *Neorickettsia* spp. in nature and different clinical signs. However, because homologous species or strain antigen provide the most sensitive serodiagnosis, identifying at least the species is still important. Even if infection is misdiagnosed with other species, tetracycline series of antibiotics are effective for all of the ehrlichial diseases, especially at early stages of infection.

Recently the author's laboratory found that one of six *N. risticii* Ohio isolates and three Kentucky isolates were divergent from *N. risticii*, type strain (ATCC VR-986), in their antigen profiles by Western immunoblot analysis and by IFA using two panels of monoclonal antibodies.[21] The isolates also are different in the base sequence of 16S rRNA[15] and translated amino acid sequences of 51-kd antigen genes[28] and in growth morphology in the cell.[22] The 51-kd protein is a unique antigenic protein cloned from the *N. risticii* genome that shows no homology to any other known protein.[76] Amino acid sequences of 51-kd protein derived from *Juga* sp. snails in California differ at 17 amino acid positions over the 179 amino acids that can be compared (90.5% identity) with those of caddisflies and horses infected by ingestion of the caddisflies in Pennsylvania. However, the 51-kd protein amino acid sequence from caddisflies in Pennsylvania differs only at 7 amino acid positions (98.6% identity) from *N. risticii* Maryland strain over the 483 amino acids that can be compared.[29] An association of heterogeneity of *N. risticii* strains and PHF vaccine failure in Virginia and Maryland was reported.[77] Thus multiple strains or subspecies of *N. risticii*, or *Neorickettsia* spp. in the field, are likely to be distinguishable by Western immunoblotting or monoclonal antibody labeling of antigens but not by IFA or ELISA serologic testing of infected horse sera. Sequencing the antigenic protein genes further clarifies these strains. The existence of divergent antigenic variants should be taken into consideration in improving the serodiagnosis and efficacy of vaccines for PHF in the field.

In summary, recommendations for the serologic confirmation of PHF include demonstration of seroconversion, a fourfold rise or fall in titer, or the presence of IgM antibody specific to *N. risticii*. One should emphasize, however, that the initial diagnosis and treatment of PHF should be made on clinical signs, negative test results for other pathogens such as salmonella, for which the use of tetracyclines may be contraindicated, and initial IFA test results if available within 1 to 2 days. Treatment should not be delayed until laboratory confirmation is obtained from a second IFA test. It is important to point out that in the field PHF and salmonellosis can occur concurrently.[70] Weak seropositive or seronegative results of vaccinated horses when they develop clinical signs compatible with PHF are useful for ruling out the possibility of this infection. Seropositive results in vaccinated horses are useless unless confirmed by a fourfold rise in titer or by a positive PCR test.

2.4.1.6.2

Isolation of *Neorickettsia risticii* and Polymerase Chain Reaction

The isolation of *N. risticii* is accomplished by inoculating buffy coat or mononuclear cell fractions of peripheral blood of affected animals into cell culture.[21,22,42] Murine monocyte-macrophage P388D$_1$ cells, human histiocytic lymphoma U-937 cells, or canine primary monocytes are used for isolating *N. risticii*.

The procedure is more sensitive than is direct observation. Even if a single organism cannot be seen in the original buffy coat smear, the organisms can be isolated by this procedure.

Isolation procedures for diagnosing infection, however, are impractical for clinical laboratories because they take too long (3 days to 1 month) relative to the rapid course of PHF and require a reasonable tissue culture technique and facility. Although positive isolation provides a definitive diagnosis, negative results do not necessarily indicate the absence of infection.

A PCR that detects 16S rRNA, *groel*, and 51-kd protein genes of *N. risticii* in peripheral blood monocytes and feces of experimentally infected animals has been developed.[26,42,78] Applicability of this test in field cases has been tested.[42] Although cell culture isolation gives superior sensitivity to PCR procedure for field specimens, PCR procedure will be used more often in the future because of its convenience.

2.4.1.6.3 Postmortem Identification of Ehrlichial Organisms

N. risticii can be demonstrated in intestinal epithelial cells and macrophages in paraffin-embedded tissue specimens with a silver stain or an immunoperoxidase procedure using a specific antibody to *N. risticii*. 102
Immunoperoxide staining detects fewer *N. risticii* than does silver staining, presumably because of partial 103
inactivation of antigens owing to fixation and paraffin embedding. However, silver staining produces background reactions in some specimens and thus is less specific than immunoperoxidase staining.[79] These procedures have not been adapted for routine diagnosis.

2.4.1.7 PATHOLOGIC FINDINGS

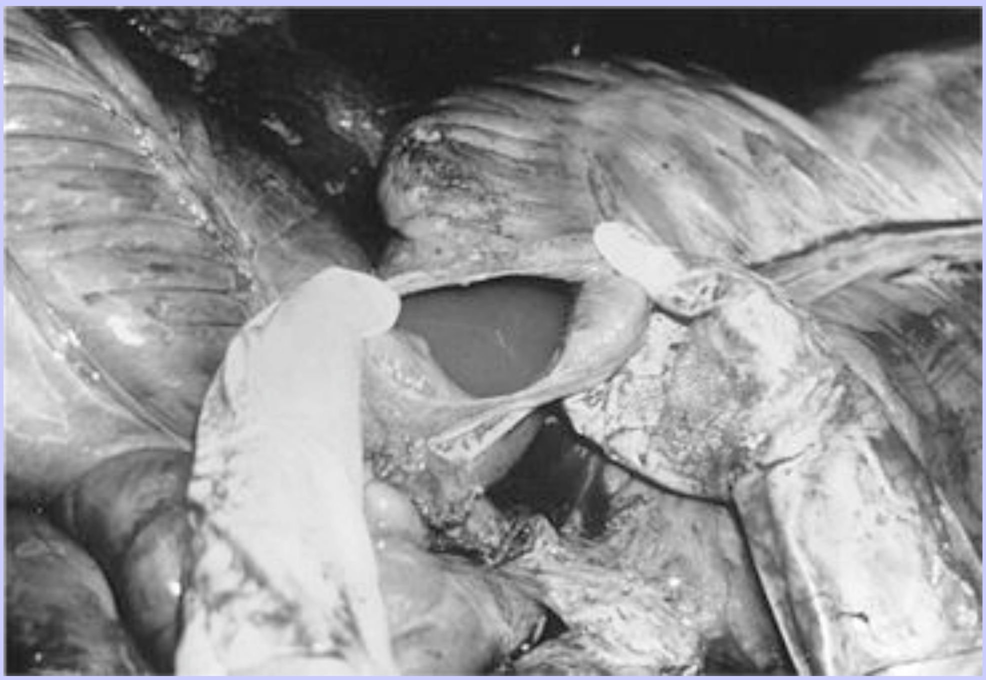
The most obvious postmortem findings in horses with PHF are the grossly distended large colon and cecum filled with watery contents (Figure 2.4-3). Few other consistent gross pathologic changes in horses with PHF occur except for patchy hyperemia along the wall of the large intestine. No destruction, foul odor, or significant inflammatory infiltration occurs such as in enterocolitis caused by salmonella, which may cause similar clinical signs or may co-infect with *N. risticii* in nature.[45] However, remarkable goblet cell mucus depletion and reduced height and increased basophilia of mucosal epithelial cells, dilation of intestinal glands, and entrapment of cellular debris in the glandular lumens are seen in experimental *N. risticii* infection.[45,71,80] Mesenteric lymph nodes are small and consist of prominent sheets of histiocytes, macrophages, occasional giant cells, and severely depleted inactive lymphoid cells.[71] Lack of severe lesions and absence of neutrophil infiltration are thus important in the differential diagnosis of PHF. The combination of lymphohistiocytic enterocolitis, hepatitis, and myocarditis in the aborted fetus at approximately 7 months gestation because of *N. risticii* infection is reported.[65,66]

2.4.1.8 THERAPY

In vitro, *N. risticii* is susceptible to doxycycline, demeclocycline, and oxytetracycline but is resistant to erythromycin and nalidixic acid.[81] As with other rickettsiae, *N. risticii* is resistant to aminoglycosides because they penetrate host cells poorly. Although oxytetracycline alone is bacteriostatic, it was found to induce lysosomal fusion with ehrlichia-containing vacuoles in P388D_1 cells,[23] thus becoming bactericidal. Oxytetracycline and doxycycline frequently correct the pyrexia and other clinical signs of PHF within 24 to 48 hours, which by itself is diagnostic.[67] Although doxycycline is more effective than is oxytetracycline in vitro

and is highly effective in mice inoculated with *N. risticii*,[81,82] oxytetracycline is preferred for the equine species because intravenous administration of doxycycline has an acute toxic effect.[83] Intravenous oxytetracycline at 6.6 mg/kg of body mass twice a day for 7 days was effective in 71% (five of seven) of experimentally infected ponies when ponies were treated after development of severe clinical signs.[67] Oxytetracycline is effective when given immediately after the development of fever but before development of diarrhea.[84] In the murine model of PHF, doxycycline, given on the fifth day, has the best effect on the immune response. When doxycycline is given on the third or seventh day after infection, immunodepression caused by *N. risticii* infection is more severe.[82] Although erythromycin or rifampin alone has a poor effect in controlling *N. risticii* infection in vitro or in infected mice,[80,81] the orally administered combination of erythromycin and rifampin has been efficacious in treating experimentally infected horses.[85]

Figure 2.4-3 Fluid-filled large colon of a horse with Potomac horse fever.



Other supportive therapy frequently is required for acutely ill horses if they are to show clinical improvement. Dehydration is corrected by the oral or intravenous administration of polyionic isotonic fluids. Brief therapy (2 to 7 days) with nonsteroidal antiinflammatory agents (e.g., phenylbutazone, flunixin, meglumine, or aspirin) for horses may be valuable early in the course of treatment to help in the management of clinical signs of PHF.[84]

2.4.1.9

PREVENTION

Ingestion of infected trematodes is probably the only means of transmission under natural circumstances, because susceptible animals housed for several months adjacent to infected animals do not have a higher incidence of the disease than those kept far from infected animals.[86] Because infection-induced immunity is

excellent[53] and a vaccine made of β-propiolactone–inactivated host cell–free *N. risticii* protects mice from homologous challenge based on clinical, pathologic, and immunologic criteria,[87] vaccination is expected to be effective in controlling PHF. Vaccines prepared from inactivated cell-cultured *N. risticii* are available for PHF from three commercial sources. Formalin-inactivated whole organism vaccine with aluminum hydroxide adjuvant has been reviewed. The vaccine is reported to cause no ill effects in horses except for swelling at the injection site in 10% of the animals.[88] Studies published in 1987 reported 78% prevention of all clinical signs except fever.[89] Protection conferred by this vaccine appears to be much shorter in duration compared with infection-induced protection. IFA titers measured after vaccination are also lower and drop rapidly in contrast to what occurs in natural infection.[88] Vaccination is not necessary for up to 2 years in the horse that has recovered from illness or has a high IFA titer from natural exposure or subclinical infection, because infection-induced immunity provides better protection than do vaccines. For nonexposed animals, considering the time required to develop immunity after vaccination, the short-lasting immunity to even the homologous strain of *N. risticii*, and the existence of antigenic variants in the field, how much benefit the vaccine will provide in the field challenge is unknown. Vaccine failures have been reported.[21,42,66,77] Therefore improvement of vaccine for PHF is desired.

103
104

Recombinant clones that produce several *N. risticii* antigenic proteins have been produced in the author's and other laboratories. Using the murine model for PHF, a combination of two recombinant clones that express 44-kd and 70-kd antigens was shown to confer protection against *N. risticii* challenge.[90] The protection was slightly less effective than the protection given by whole *N. risticii* antigen. The efficacy of recombinant antigens for protecting horses from PHF has not been reported.

2.4.2 Equine Ehrlichiosis

2.4.2.1 GEOGRAPHIC DISTRIBUTION

Equine ehrlichiosis and *Anaplasma phagocytophilum* in the cytoplasm of blood neutrophils and eosinophils in affected horses were reported initially in 1969.[91] The disease has been observed chiefly in California. In addition, sporadic cases have been reported in Colorado, Illinois, Florida, Washington, and New Jersey and also in Germany,[92] Switzerland,[93] Sweden,[94] and Israel.[95] In the United States the disease occurs much less frequently than does PHF.

2.4.2.2 CAUSE

A. phagocytophilum is classified along with *A. marginale*, which causes infectious anemia in cattle by infecting erythrocytes, and *A. platys*, which causes canine cyclic thrombocytopenia by infecting platelets, in the family Anaplasmataceae. Because 16S rRNA gene sequences differ only up to three bases among former *Ehrlichia equi; E. phagocytophila*, which infects ruminants (primarily sheep and goats in Europe); and recently discovered human granulocytic ehrlichiosis (HGE) agent, these organisms are now considered strains of *A. phagocytophilum*.[4] By 16S rRNA gene sequence comparison, relatedness between *N. risticii* and *A. phagocytophilum* is low, approximately 83.3%. *A. phagocytophilum* has been cultured in vitro using the tick-embryo cell line IDE8[96] and a human promyelocytic leukemia cell line HL60.[97] Contrary to previous speculation by some researchers, *A. phagocytophilum* is a distinct species different from *E. ewingii* (another granulocytic ehrlichia that infects dogs in the United States) and has a 16S rRNA gene sequence homology of 92.4%.

A. phagocytophilum appears as round, dark purple, small dots or loose aggregates that look like mulberries (morulae) in the cytoplasm of blood granulocytes, primarily in neutrophils and eosinophils by Romanowsky staining.[91] By electron microscopy, several loosely packed ovoid, round, or rod-shaped *A. phagocytophilum* organisms are seen in several membrane-lined vacuoles of equine neutrophils and eosinophils.[98] The size of vacuoles ranges from 1.5 to 5 μm in diameter.[99]

2.4.2.3 EPIZOOTIOLOGY

In contrast to PHF, equine ehrlichiosis occurs during late fall, winter, and spring. Like PHF, in some areas equine ehrlichiosis is endemic and in others the disease is absent. In one seroepidemiologic survey, horses residing in the foothills of northern California had greater exposure to *A. phagocytophilum* than did those residing in the Sacramento Valley.[100] Because most seropositive horses in this study were healthy, subclinical infection with *A. phagocytophilum* seems to occur as PHF. Recent findings indicate that the western black-legged tick, *Ixodes pacificus*, is able to transmit *A. phagocytophilum* and may act as a competent vector in the field.[101,102] *A. phagocytophilum* can cause parasitemia in dogs, cats, goats, sheep, and nonhuman primates with mild to no clinical signs.[91,103,104] Cattle, rats, mice, guinea pigs, hamsters, or rabbits are not susceptible to infection.[103,104] Gribble suggested that the horse may be an accidental host, based on the low incidence of the disease.[91] Whether other species of animals can serve as a reservoir for equine ehrlichiosis is unknown, although white-footed mice recently were shown to serve as an enzootic reservoir of the HGE agent.[105]

A structural protein of *A. phagocytophilum* called *ank* has repeats in amino acids that are similar to the repeats within the human erythrocyte ankyrin protein. Comparison of these amino acid sequences in *A. phagocytophilum* isolated from horses, a dog, cattle, ticks, and human patients from several geographic regions in the United States and Europe revealed that the isolates are heterogeneous and not segregated by host animal species, but rather segregated by geographic locations.[106,107] Intravenous inoculation of horses with infected human blood produces a disease indistinguishable from that caused by *A. phagocytophilum*,[108] 104
and like *N. risticii*, diverse gene sequences detected among horse isolates indicate equine ehrlichiosis is caused 105
by multiple strains of organisms.

2.4.2.4 PATHOGENESIS AND IMMUNE RESPONSE

Infected animals develop antibody detectable by IFA, and leukocytes from infected animals show inhibition of migration when mixed with *A. phagocytophilum* antigen. Because *A. phagocytophilum* from the horse has not been propagated in vitro in sufficient quantity, an antigen prepared from the buffy coat cells of an experimentally infected horse is used as the antigen for immunologic studies.[109] Spontaneously recovered animals are immune to reinfection from 2.5 to 20 months. Maternal antibody protects foals from the disease for up to 2 months, but not from establishment of infection. When an immune mare was challenged, small numbers of infected neutrophils were seen in a 15-day-old foal born to the mare.[91] Oxytetracycline treatment eliminates *A. phagocytophilum* from horses, but rechallenge induces minimal clinical signs, suggesting the development of protective immunity in the recovered horse. Although the blood of recovered horses is reported not to be infectious, blood collected from ponies at 81 or 114 days after primary infection with *A. phagocytophilum* induced mild clinical signs (fever and mild thrombocytopenia) in susceptible recipient ponies but did not protect the recipient animals against a second challenge 100 days later. Thus *A.*

phagocytophilum appears to persist in small numbers despite the concomitant presence of antibodies and the demonstrable inhibition of leukocyte migration.[109]

2.4.2.5 CLINICAL FINDINGS

With experimental transmission using fresh blood from an infected horse, the incubation period for equine ehrlichiosis is 1 to 9 days.[91] However, when naturally infected *I. pacificus* ticks are attached, clinical signs appeared at 18 or 25 days after exposure in two horses and one horse remained normal. All three horses were infected as determined by PCR, but sequences of 16S rRNA gene of *A. phagocytophilum* in three horses were different from that of the type strain, indicating strain and disease variations.[102] Clinical signs of disease include fever lasting 1 to 9 days, depression, partial anorexia, limb edema, petechiae, icterus, ataxia, and reluctance to move.[105] In contrast to *N. risticii* infection, laminitis does not develop in equine ehrlichiosis.[110] Experimental inoculation of seven pregnant mares caused clinical signs of various severity, but none of the mares aborted. Hematologic changes observed included thrombocytopenia, decreased packed cell volume, and significant leukopenia, first involving lymphocytes and then granulocytes. The disease is inapparent to mild and is usually not fatal except for injury resulting from ataxia or secondary infection. *A. phagocytophilum* morulae are found in the cytoplasm of neutrophils and eosinophils only during the acute phase of the disease. The infection rate of peripheral blood neutrophils varies from 0.5% to 73%.[91] Chronic cases have not been reported.

2.4.2.6 DIAGNOSIS

Direct microscopic examination of Romanowsky-stained peripheral blood buffy coat smears (the author prefers Giemsa or Diff-Quik) is simple and inexpensive and provides a permanent record. *A. phagocytophilum* can be seen in granulocytes of buffy coat smears during the acute phase of the disease at 1000 times magnification. When more than three ehrlichial inclusion bodies (morulae) are seen, the diagnosis is considered definitive.[110] Culture isolation of *A. phagocytophilum* from the blood of horses rarely is performed, although *A. phagocytophilum* is isolated routinely from human patients with HGE. An IFA test using the buffy coat cells of the infected horse as the antigen has been developed and has been useful in detecting and titrating antibody in recovered horses.[109] Infected ponies become seropositive by IFA test at 21 days after inoculation, and antibody titers as high as 1:1280 can be detected at day 75 after inoculation. Major surface protein antigens of approximately 44 kd of *A. phagocytophilum* from an HGE patient were cloned in the author's laboratory[111] and others and have been used for serodiagnosis by dot blot Western immunoblot and ELISA of human patients. Because human and horse isolates are highly antigenically cross-reactive, these serologic assays are applicable for diagnosis of equine ehrlichiosis. Nested PCR has been developed for detection of *A. phagocytophilum* 16S rRNA gene in horse blood and ticks.[112] The genes *ank* and *p44* also are used for PCR diagnosis of human HGE patients. None of these methods distinguishes among *A. phagocytophilum* strains (former *E. equi*, the HGE agent, and *E. phagocytophila*) infection.

2.4.2.7 PATHOLOGIC FINDINGS

The characteristic gross lesions are petechial hemorrhages and edema accompanied by proliferative and necrotizing vasculitis of small arteries and veins in the legs. In mature males, orchitis also may be seen.[91]

2.4.2.8

THERAPY

Intravenous administration of oxytetracycline at a dosage of 7 mg/kg of body mass is reported to be effective in treating *A. phagocytophilum* infection.[110] After the initial 48 hours of treatment with oxytetracycline, defervescence is seen in all horses treated.

2.4.2.9

PREVENTION

Because *A. phagocytophilum* most likely is transmitted by *Ixodes* sp. ticks, tick repellent and insecticide are expected to be effective for prevention. A vaccine has not been developed for this disease.

TABLE 2.4-1 Comparison of Biologic Features of *Neorickettsia risticii* and *Anaplasma phagocytophilum*

FEATURE	*N. RISTICII*	*A. PHAGOCYTOPHILUM*
Distribution	United States, Canada, Europe	United States, Europe
Natural host	Horse	Horse, human, sheep, goat, dog, mouse
Experimental host	Mouse, nonhuman primate, cat, dog	Cat, dog, sheep, goat, nonhuman primate but not rat, guinea pig, rabbit, cow
Host cell	Monocyte/macrophage, intestinal epithelial cells, mast cells	Neutrophils, eosinophils
Appearance of inclusion	Individually tightly enveloped by host membrane or densely packed morulae (some of recent Ohio and Kentucky isolates)	Loosely packed small morulae

TABLE 2.4-2 Comparison of Clinical Features of Potomac Horse Fever and Equine Ehrlichiosis

CHARACTERISTIC	POTOMAC HORSE FEVER	EQUINE EHRLICHIOSIS
Mortality	Low to high	None
Acute disease	Yes	Yes
Chronic disease	No	No
Severity	Mild to severe	Mild to moderate
Leukopenia	Yes	Yes
Thrombocytopenia	Yes/no	Yes
Anemia	Yes/no	Yes
Pyrexia; anorexia; depression	Yes	Yes
Laminitis	Yes/no	No
Diarrhea	Yes/no	No
Abortion	Yes/no	No
Ehrlichia	Rarely seen in the blood	Blood granulocytes
Differential diagnosis	Colitis X	Encephalitis
	Salmonellosis	Liver disease
	Endotoxic shock	Purpura hemorrhagica
	Antibiotic-associated diarrhea	Equine infectious anemia
	Dietary changes	Equine viral arteritis
	Intoxications	

105

106

2.4.3 Summary

Tables 2.4-1 and 2.4-2 summarize the biologic and clinical features of PHF and equine ehrlichiosis.

In recent years, because of outbreaks of PHF in the United States and discovery of the HGE agent, a strain of *A. phagocytophilum*, awareness has increased of the importance of rickettsial diseases in horses. With rickettsial diseases, wild animals and vector arthropods or helminths are usually reservoirs of rickettsiae, and domestic animals and human beings are accidental dead-end hosts. Because environmental exposure of horses to vectors and reservoirs is high, improving diagnostic, therapeutic, and vaccination procedures is important.

3 CHAPTER 3 CLINICAL APPROACH TO COMMONLY ENCOUNTERED PROBLEMS

Melissa T. Hines

3.1 3.1—Syncope and Weakness

Mark V. Crisman

Syncope is a clinical syndrome consisting of a generalized weakness, sudden collapse, and a transient cessation of consciousness. Syncopal episodes are uncommon in horses, and generally few or no premonitory warning or presyncopal (faintness) signs are evident to the rider or handler. The subsequent loss of consciousness and collapse may be potentially harmful or dangerous to the horse and the rider. Despite the infrequent reports of true syncopal episodes in horses, the clinical signs are sufficiently dramatic to cause great concern on the part of the owner. Syncope in horses has been virtually unstudied. Consequently, most of the following information has been drawn from studies of persons and other animal species.

Although presyncopal signs have been well described in human beings (i.e., dizziness, yawning, confusion, and spots before the eyes), these signs are generally not evident in horses. Horses may stumble initially and go down or collapse completely. The depth and duration of unconsciousness may vary, but generally unconsciousness lasts for a few minutes. Horses may be slightly unsteady or struggle during recovery. After a syncopal attack, the horse will completely recover and appear normal.

3.1.1 Pathophysiology

Syncope results from a sudden reduction in cerebral blood flow and subsequent cerebral ischemia. Cerebral blood flow is maintained primarily by arterial blood pressure and cerebrovascular resistance. In response to falling or rising systemic blood pressure, the cerebral blood flow autoregulatory mechanism automatically regulates cerebral vessels to constrict or dilate. This control phenomenon maintains a constant cerebral blood flow despite fluctuations in arterial blood pressure, whether or not these fluctuations are physiologic or pathologic. If perfusion pressure in human beings falls below 60 mm Hg, the cerebral blood flow autoregulatory mechanism may fail. Mean resting arterial pressure measured at the carotid artery in horses has been reported to be 97 ± 12 mm Hg at a heart rate of 42 ± 10 beats/min.[1] Systolic pressure in horses experiencing syncope has not been determined.

Disturbances in oxygen supply to the brain generally result from three primary causes: anoxia, anemia, and ischemia. Although a variety of conditions or diseases may cause these disturbances, all three potentially deprive the brain of its critical oxygen supply.[2] Anoxia generally is described as insufficient oxygen reaching the blood so that arterial oxygen content and tension are low. This insufficiency results from an inability of oxygen to cross the alveolar membrane (e.g., pulmonary disease) or low oxygen tension in the environment (e.g., high altitude). In situations of mild hypoxia, the cerebral blood flow autoregulatory mechanism maintains oxygen delivery to the brain. When the hypoxia is severe or the compensatory mechanism fails, cerebral hypoxia occurs and syncope may result.

Anemia is defined functionally as a decreased oxygen-carrying capacity of the blood. This may be characterized 111
by several mechanisms, including a reduction in the amount of hemoglobin available to bind and transport 112
oxygen or changes in hemoglobin that interfere with oxygen binding (e.g., methemoglobin). If the anemia is

severe, the oxygen concentration drops below the metabolic requirements of the brain despite increased cerebral blood flow.

Finally, cerebral ischemia results when cerebral blood flow is insufficient to supply cerebral tissue. Any disease that greatly reduces cardiac output, such as myocardial infarction or an arrhythmia, ultimately may result in cerebral ischemia. If any of these aforementioned conditions occurs and cerebral blood flow is interrupted or stops with resultant cerebral underperfusion, consciousness is lost. If tissue oxygenation is restored immediately, consciousness generally returns quickly without sequelae.

Areas of the brain that maintain or control consciousness have been the subject of much debate and research. Generally, the level of activity of the brain (alertness) is maintained through sensory input to the ascending reticular activating system in the rostral brainstem, thalamus, and cerebral cortex. More specifically, the bulboreticular facilitatory area within the reticular substance of the middle and lateral pons and mesencephalon is considered to be the central driving component of the excitatory area of the brain. Recent studies have identified the role of the midbrain reticular formation and the thalamic intralaminar nuclei in maintaining consciousness and arousal in animals and human beings.[3] Syncope may result if regional cerebral blood flow to this area is disrupted for any reason.

In horses, syncope may be cardiogenic or extracardiac (neurocardiogenic) in origin. The primary cause of syncope in horses is generally cardiovascular disease. Cardiogenic syncope may result from (1) myocardial disease, (2) cardiac dysrhythmias (i.e., atrial fibrillation and third-degree heart block), (3) congenital heart disease, (4) pulmonary hypertension or stenosis, and (5) pericardial disease. Although many of these conditions are uncommon in horses, atrial fibrillation has been associated with several reports of syncope.[4]

Cardiovascular disease, resulting in an inability to regulate heart rate or in stroke volume, ultimately decreases cardiac output. Atrial fibrillation can lead to heart rates greater than 240 beats/min with submaximal exercise. The lack of effective atrial contraction prevents complete ventricular filling at the end of diastole, thus causing a great reduction in effective cardiac output. Complete heart block may be persistent or intermittent and also has been associated with syncopal episodes in horses. When the block is complete and the pacemaker below the block fails to function, syncope occurs. This situation has been reported in human beings and horses as Morgagni-Adams-Stokes syndrome. This syndrome is the most frequent arrhythmic cause of syncope in human beings.[5] Morgagni-Stokes-Adams attacks result from an advanced atrioventricular block and usually involve a momentary sense of weakness followed by an abrupt loss of consciousness. After cardiac standstill or prolonged periods of asystole, unconsciousness results from cerebral ischemia. These “cardiac faints” have been reported to occur several times a day in human beings. Additional, less common causes of cardiogenic syncope usually involve the distal conduction system (His-Purkinje system) and may be persistent or episodic. Heart block involving the atrioventricular node or proximal conduction system may be congenital or drug induced (e.g., digitalis). Sick sinus syndrome, a condition described in elderly human beings, involves impaired sinoatrial impulse formation or conduction and has been associated with cerebral anoxia. With any of these conditions, cardiac output does not increase sufficiently during skeletal muscle exercise to meet peripheral oxygen demands. Blood preferentially flows to exercising muscle, resulting in systemic arterial hypotension, which results in cerebral ischemia leading to weakness or syncope.

Extracardiac causes of syncope indirectly may involve the cardiovascular system and were referred to previously as vasovagal or vasodepressor syncope. The term *neurocardiogenic syncope* more accurately describes this phenomenon. Neurocardiogenic syncope is the most common type of syncope reported in human beings and often is precipitated by stress or pain.[6] Although not specifically described in horses, a similar mechanism of collapse likely may exist. The critical cardiovascular features include hypotension and paradoxical sinus

bradycardia, heart block, or sinus arrest after sympathetic excitation. Additionally, cardiac asystole may occur as an extreme manifestation of neurocardiogenic syncope. The mediating mechanisms of neurocardiogenic syncope are not well understood; however, several theories have been proposed. Hypercontractile states may cause excessive stimulation of the myocardial mechanoreceptors (C fibers) located in the left ventricle. The result is an exaggerated parasympathetic afferent signal carried by the vagus and glossopharyngeal nerves with a subsequent decrease in sympathetic tone. Inhibition of sympathetic vasoco strictor activity results in vasodilation, which may be especially evident during periods of vigorous activity and increased heart rates and blood pressure. The excess vagal activity produces bradycardia and a decrease in cardiac output. This combination, along with a decrease in peripheral vascular resistance, ultimately leads to syncope.

Regardless of the specific cause, syncope results from a sudden fall in cerebral blood flow. The loss of consciousness is caused by a reduction of oxygenation to the parts of the brain that maintain consciousness. In horses, syncope usually is caused by a fall in systemic blood pressure resulting from a decrease in cardiac output. 112

Additional, less common causes of syncope in horses may include neurologic disease from space-occupying 113
lesions or increased intracranial pressure. Syncopal episodes have been reported in foals with severe respiratory or congenital heart disease.[7] After minimal exercise or restraint in these foals, hypoxia and subsequently reduced cerebral blood flow may result in syncope. Certain drugs, specifically phenothiazine tranquilizers (acepromazine), have been reported to cause syncope in horses. These tranquilizers produce antiadrenergic effects primarily through α_1-blockade with resultant vasodilation and hypotension. If phenothiazine tranquilizers are administered to severely hypovolemic horses or to horses that have hemorrhaged, severe hypotension and syncope may result.

Several disorders often are confused with syncope and should be differentiated carefully by an accurate history and thorough physical examination. These disorders include (1) epilepsy, (2) hypoglycemia, (3) narcolepsy and cataplexy, (4) cerebrovascular disease, and (5) hyperkalemic periodic paralysis.

Epileptic seizures generally differ from syncope in that they have immediate onset and involve loss of consciousness, tonic and clonic convulsive activity with opisthotonos, and changes in visceral function (urination and defecation). Seizures commonly last for several minutes and often are followed by a postictal phase in which the horse may pace, appear blind, and not recognize its surroundings.

Metabolic disturbances such as hypoglycemia frequently are observed in neonatal foals and may be associated with weakness or syncopal-like episodes. Typically, foals are premature or are subject to perinatal stress with subsequent increased glucose use following hypoxia or sepsis. Serum glucose determination is necessary to evaluate hypoglycemia.

Narcolepsy, an abnormal sleep tendency, and cataplexy occasionally may be difficult to distinguish from syncope as a cause of unconsciousness. Attacks of narcolepsy or cataplexy may be preceded by signs of weakness (buckling at the knees) followed by total collapse and areflexia. Rapid eye movements may occur with an absence of spinal reflexes. No other neurologic abnormalities are observed between attacks, although animals may appear sleepy between episodes. Provocative testing with physostigmine (0.05 mg/kg) may induce narcoleptic attacks and might be helpful in differentiating syncope from narcolepsy or cataplexy.

Cerebrovascular disease associated with head trauma and subarachnoid hemorrhage may cause temporary unconsciousness in horses. Clinical signs resulting from brain trauma generally are associated with focal cerebral dysfunction and therefore are readily distinguishable from syncope.

Hyperkalemic periodic paralysis causes weakness and collapse without alterations in consciousness. This autosomal dominant disorder has been reported in certain lines of registered Quarter Horses, Paints, and Appaloosas. A reliable DNA-based test is available to diagnose hyperkalemic periodic paralysis in horses.

3.1.2 Evaluation of Syncope

A thorough evaluation of syncope in the horse consists of the following:

1. *History:* Emphasis should be placed on obtaining a detailed history. The onset and the duration of the problem along with performance history should be determined.
2. *Physical examination:* After a thorough physical examination and determination of vital signs, a detailed cardiovascular and neurologic examination should be performed. In addition to heart rate at rest and pulse characteristics, a thorough cardiac auscultation should be performed in a quiet room to identify any murmurs or cardiac dysrhythmias. An electrocardiogram and echocardiogram also provide valuable information. A neurologic examination should evaluate reflexes and sensory and motor function carefully to identify any central or peripheral neuropathies.
3. *Complete blood count and biochemical profile:* To rule out other potential causes of syncopelike episodes (e.g., hypoglycemia and sepsis), a complete blood count and biochemical profile should be performed. Additionally, serum lactate dehydrogenase (isoenzymes 1 and 2) and creatine kinase (CK-2) concentration determinations may be helpful in identifying cardiac dysfunction.
4. *Exercise/stress test:* A thorough cardiac evaluation should be performed following strenuous exercise, including auscultation and an electrocardiogram. If available, a high-speed treadmill may be helpful in this phase of the evaluation. If any cardiac abnormalities are detected on physical examination, exercise testing on a treadmill will allow a more thorough evaluation of the cardiovascular system, although care must be taken to ensure that such testing does not exacerbate the condition of the horse.

Diagnosis of the cause of syncope in horses is not always easy, because the cause should be considered a symptom complex rather than a primary disease. In addition to the infrequent reports of syncope, the history is often vague and the neurologic and cardiovascular examinations may not lead to a specific cause. Even in the absence of apparently overt cardiovascular disease (e.g., atrial fibrillation), cardiac dysrhythmias cannot be excluded as the possible cause of syncope.

3.1.3 Treatment of Syncope

Options for treating syncope in horses are limited. The frequency of the syncopal attacks and the underlying 113
cause (i.e., cardiogenic or neurocardiogenic) may determine if a course of treatment should be undertaken. 114
Generally, treatment of syncope should be directed toward preventing or correcting the cause of the decreased cerebral perfusion. An accurate pathophysiologic diagnosis is essential for treating cardiogenic syncope. A few reports in the literature indicate successful treatment of syncope in horses associated with atrial fibrillation.[4] A horse with a complete heart block returned to work after implantation of a transvenous cardiac pacing system.[8]

3.2—Polyuria and Polydipsia

Catherine W. Kohn

Bernard Hansen

The complaint of excessive urination and drinking may be encountered with some frequency in equine practice. Before pursuing a lengthy diagnostic workup, verifying that 24-hour urine production and voluntary water consumption exceed reference ranges is important. Urine production in adult horses may range from 15 to 30 ml/kg/day, and values as high as 48 ml/kg/day have been reported.[1–4] Daily urine volume is affected by diet; more water is lost in the urine in horses fed pelleted diets and legume hays than in horses fed grass hay. The latter excrete more water in feces.[5,6] Generally, any component of the diet that increases renal solute load increases urine volume (e.g., high salt content in the diet). Voluntary water intake also is affected by the ambient temperature (Table 3.2-1). When temperatures are high and evaporative water losses increase to cool the horse, voluntary water intake also increases. Diet and climatic conditions therefore must be considered when interpreting water consumption and urine production data. Water requirements are proportional to metabolic body size rather than to body mass. Thus larger horses, particularly draft breeds, require less water per kilogram than do smaller horses, ponies, or miniature horses. In addition, fat is low in water content compared with lean body tissue, and fat animals require proportionately less water than do lean animals.[7]

Some owners may misinterpret polyalkiuria (frequent urination usually of small volume) as polyuria. Quantitative collection of urine for a 24-hour period may be required to verify excessive urine production. Several simple collection apparatuses have been described.[8,9]

3.2.1 Maintenance of Water Balance in Health

Maintenance of water homeostasis depends on establishing a balance between intake and excretion such that plasma osmolality remains constant (within approximately 2% of normal).[10] The primary determinant of renal water excretion is antidiuretic hormone (ADH).[11] ADH is a polypeptide synthesized in three nuclei in the hypothalamus (suprachiasmatic, paraventricular, and supraoptic nuclei)[12] and transported from the latter two 114
nuclei in secretory granules down axons of the supraopticohypophyseal tract into the posterior lobe of the 115
pituitary where ADH is stored. Some ADH enters the cerebrospinal fluid or portal capillaries of the median eminence from the paraventricular nucleus.[11] In addition, neurons from the suprachiasmatic nucleus deposit ADH in other areas in the central nervous system.[12] In human beings, lesions of the posterior pituitary or supraopticohypophyseal tract below the median eminence usually do not lead to permanent central diabetes insipidus because ADH still has access to systemic circulation in these cases.[11] The clinical importance of these anatomic relationships in horses is not known.

TABLE 3.2-1 Voluntary Water Consumption in Healthy Horses

25°C (77°F)	70	31.5

Data from Tasker JB: Fluid and electrolyte studies in the horse. III. Intake and output of water, sodium and potassium in normal horses, *Cornell Vet* 57:649–657, 1967; Rose BD: *Clinical physiology acid-base and electrolyte disorders,* New York, 1989, McGraw-Hill Information Services; and Groenedyk S, English PB, Abetz I: External balance of water and electrolytes in the horse, *Equine Vet J* 20:189–193, 1988.

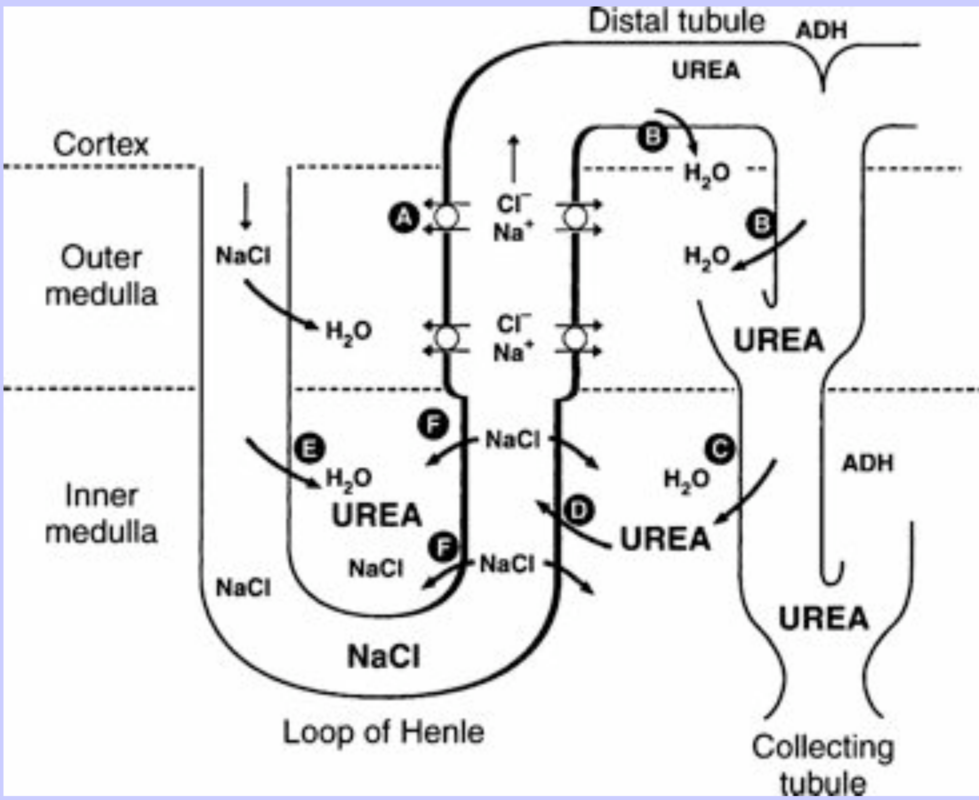
ADH increases renal water reabsorption and urine osmolality by augmenting water permeability of luminal membranes of cortical and medullary collecting tubules. ADH augments urea, and in some species NaCl, accumulation in the interstitium, therefore promoting medullary hypertonicity. The primary stimuli for ADH release are plasma hyperosmolality and depletion of the effective circulating blood volume. Osmoreceptors in the hypothalamus detect changes in plasma osmolality of as little as 1%.[11] Although the threshold for ADH release in the horse is not known, 24-hour water deprivation in healthy ponies resulted in approximately an 8 mOsm/kg increase in plasma osmolality (about 3%), from 287 ±3 mOsm/kg to 295 ± 4 mOsm/kg, which was associated with an increase in plasma ADH concentration from 1.53 ± 0.36 pg/ml to 4.32 ± 1.12 pg/ml.[13] In another study of ponies, water deprivation for 19 hours resulted in an increase in plasma osmolality from 297 ± 1 mOsm/L to 306 ± 2 mOsm/L.[14] In human beings, plasma osmolalities of 280 to 290 mOsm/L stimulate ADH release. The organs that sense changes in effective circulating blood volume include arterial and left atrial baroreceptors. These stretch receptors function indirectly as volume sensors by responding to the reductions in intraluminal pressure that typically accompany loss of plasma volume. Reduced activation of these receptors by hypovolemia or heart failure is a potent cause of ADH release, even in the absence of increased plasma osmolality. ADH secretion also may be stimulated by stress (pain), nausea, hyp glycemia, and certain drugs including morphine and lithium.[11]

When the need for water in body fluids cannot be met by conservation via the renal/ADH axis, thirst is stimulated. Thirst is regulated primarily by plasma tonicity; however, in human beings the threshold for stimulation of thirst is approximately 2 to 5 mOsm/kg greater than that for stimulation of ADH release.[11] Thirst is controlled by osmosensitive neurons in close proximity in the hypothalamus to osmoreceptors that mediate ADH secretion.[12] Thirst is sensed peripherally by oropharyngeal mechanoreceptors as dryness of the mouth. Thirst also may be stimulated by volume depletion through an incompletely understood mechanism. Experimental ponies drank when their plasma osmolalities increased by 3% after water deprivation, when plasma Na concentrations increased by approximately 5%, and after induction of a plasma volume deficit of 6%.[14]

3.2.2 Mechanism of Urine Concentration

For the kidney to make concentrated urine, ADH must be produced, the renal collecting tubules must respond to ADH, and the renal medullary interstitium must be hypertonic. Generation of medullary hypertonicity is initiated in the thick ascending limb of the loop of Henle by active transport of NaCl out of the lumen. Because the thick ascending limb is impermeable to water, active resorption of NaCl results in hypotonicity of the fluid entering the distal tubule in the renal cortex (Figure 3.2-1, *A*). The distal tubules and cortical portions of the collecting ducts are permeable to water (Figure 3.2-1, *B*), which is reabsorbed down its concentration gradient into the interstitium. Reabsorbed water is transported rapidly out of the interstitium by the extensive cortical capillary network, and interstitial hypertonicity is preserved. Urea remains in the lumen of the distal tubule and cortical collecting duct and is concentrated further. Luminal fluid flows into the medullary collecting duct, which is permeable to water and urea when under the influence of ADH (Figure 3.2-1, *C*). Water is reabsorbed down its progressively steeper concentration gradient as luminal fluid moves through the medullary collecting ducts. Some urea also is reabsorbed into the interstitium. Reabsorbed water is removed efficiently by the vasa recta in the renal medulla. Because these blood vessels also are arranged in a hairpin loop, minimal loss of medullary interstitial solute occurs with water removal. Some reabsorbed urea enters the loop of Henle (Figure 3.2-1, *D*) and thus is recycled, helping to maintain medullary hypertonicity. In the absence of ADH, the collecting ducts are relatively impermeable to water and urea, resulting in water and urea loss in urine and reduction of medullary solute. Prolonged diuresis of any cause may result in the loss of medullary hypertonicity (medullary washout) with subsequent impairment of renal concentrating ability. Water is reabsorbed down its concentration gradient from the thin descending limb of the loop of Henle (Figure 3.2-1, *E*) as a consequence of medullary hypertonicity. This segment of the nephron is impermeable to NaCl and urea, thus the osmolality of luminal fluid in the most distal portion of the loop approaches that of the interstitium. The thin ascending limb of the loop of Henle is permeable to NaCl, which diffuses down its concentration gradient into the interstitium (Figure 3.2-1, *F*). As previously mentioned, this segment is also permeable to urea, and some interstitial urea enters the tubule 115
lumen by diffusion down its concentration gradient. Luminal fluid entering the thick ascending limb of the loop 116
of Henle is thus hypotonic to the interstitium.

Figure 3.2-1 The countercurrent hypothesis identifies the roles of sodium chloride and urea transport in the generation of concentrated urine. From Hansen B: Polyuria and polydipsia. In Fenner WR: *Quick reference to veterinary medicine,* ed 2, Philadelphia, 1991, JB Lippincott. Adapted from Jamison RL, Maffly RH: The urinary concentration mechanism, *N Engl J Med* 295:1059-1067, 1976.)



When luminal fluid reaches the thick ascending limb of the loop of Henle, approximately 80% of the glomerular filtrate has been reabsorbed. Therefore only 20% of the glomerular filtrate is available for reabsorption via the action of ADH.[15,16]

3.2.3 Primary Polydipsia

Excessive water intake may result in water diuresis. Primary polydipsia has been described in horses residing in the southern United States during months when ambient temperature and humidity are high. Apparent psychogenic polydipsia may result from boredom, especially in stalled, young horses.[8] Psychogenic polydipsia also has been reported anecdotally in horses with chronic liver disease and central nervous system signs that had been treated with intravenous fluids.[17] Primary disorders of thirst are poorly understood in horses.

3.2.4 Causes of Polyuria With Secondary Polydipsia

Increased urine flow may be induced by solute or water diuresis (Box 3.2-1). Solute diuresis results in increased urine flow because of excessive renal excretion of a nonreabsorbed solute such as glucose or sodium. During solute diuresis, the urine osmolality is equal to or higher than the plasma osmolality. Primary renal insufficiency or failure (33% or fewer intact nephrons) result in solute diuresis, because each functional nephron must filter an increased amount of solute to maintain daily obligatory solute excretion. Fractional clearances of solutes such as Na, K, and Cl therefore appropriately increase. Solute diuresis caused by glucosuria occurs in hyperglycemic horses when the maximal renal reabsorptive capacity for glucose is exceeded (180 to 200 mg/dl).[18] Solute diuresis caused by glucosuria has been reported in horses with pituitary adenoma and in a hyperglycemic horse with bilateral granulosa cell tumors.[19,20] Primary diabetes mellitus, a common cause of hyperglycemia and glucosuria in other species, is uncommon in the horse, although type 2 diabetes mellitus was diagnosed in a 15-year-old Quarter Horse mare.[21] Primary renal tubular glucosuria caused by a defect in proximal tubular glucose reabsorption (as is seen in Basenji dogs with Fanconi-like syndrome)[15] has not been reported in horses. Psychogenic salt consumption also has been reported to cause solute diuresis in a horse.[22] Postobstructive solute diuresis is not diagnosed commonly in horses because nephrolithiasis and ureterolithiasis are uncommon; when they occur, the condition is often bilateral and associated with chronic renal failure, and treatment is usually unsuccessful.[23,24]

Decreased water resorption in the collecting tubules or inappropriately large voluntary water intake causes water diuresis. The osmolality of the urine during water diuresis is less than that of plasma. Water diuresis may be caused by insufficient ADH secretion, insensitivity of the receptors of the distal collecting duct and collecting tubules to the action of ADH, renal medullary solute washout, or apparent psychogenic polydipsia. Insufficient secretion of ADH (central diabetes insipidus) may be associated with adenoma of the pars intermedia of horses but has never been documented[25] and with head trauma and potassium depletion in other species. A case of idiopathic central diabetes insipidus was reported in a Welsh pony.[26] Insensitivity of collecting duct receptors to ADH may occur during endotoxemia and hyperadrenocorticism (glucocorticoid excess associated with tumors of the pars intermedia). In other species, potassium depletion, hypercalcemia, and the administration of certain drugs (including gentamicin) have been reported to cause insensitivity of the collecting duct receptors to ADH.[15] Congenital diabetes insipidus also has been reported in other species.[26] True nephrogenic diabetes insipidus implies isolated dysfunction of response to ADH by collecting tubules that are not associated with other structural or metabolic lesions of the kidney. The occurrence of nephrogenic diabetes insipidus in two sibling Thoroughbred colts has suggested that the condition might be heritable in some horses.[27] Renal medullary 116
washout (loss of medullary Na, Cl, and urea) leading to water diuresis may result from chronic diuresis of any 117
cause. Diuresis is associated with increased tubular flow rates and inability to resorb sodium and urea adequately from the tubular lumen. Enhanced medullary blood flow may deplete medullary solute further. Water diuresis also has been reported in association with pyometra, hypoadrenocorticism (chronic renal sodium loss), chronic liver disease (increased aldosterone concentration promotes sodium retention, smaller daily load of urea for excretion caused by decreased conversion of ammonia to urea), primary polycythemia, hypercalcemia, and potassium depletion in other species.[15]

3.2.4.1 BOX 3.2-1 CAUSES OF POLYURIA AND POLYDIPSIA

3.2.4.1.1 Solute Diuresis

Primary renal insufficiency or failure

Glucosuria (adenoma of the pars intermedia of the pituitary)

Psychogenic salt consumption

Diabetes mellitus

Postobstructive diuresis

3.2.4.1.2 Water Diuresis

Insufficient antidiuretic hormone (central diabetes insipidus)

- Adenoma of the pars intermedia of the pituitary
- Head trauma
- (Potassium depletion)*

Insufficient response of collecting ducts to antidiuretic hormone

Acquired nephrogenic diabetes insipidus

- Hyperadrenocorticism (glucocorticoid excess with adenoma of the pars intermedia of the pituitary)
- Endotoxemia
- (Drugs: gentamicin, lithium, methoxyflurane, amphotericin B, propoxyphene, etc.)

(Congenital nephrogenic diabetes insipidus)

Renal medullary solute washout

- Chronic diuresis of any cause
- Inappropriate renal tubular sodium handling

Apparent psychogenic polydipsia

(Chronic liver disease)

(Polycythemia)

(Pyometra)

(Hypercalcemia)

(Potassium depletion)

3.2.4.1.3

Iatrogenic

Intravenous fluid therapy

Excess dietary salt

Drugs:

- Diuretics
- Glucocorticoids
- (Drugs causing acquired diabetes insipidus)

Modified from Hansen B: Polyuria and polydipsia. In Fenner WR: *Quick reference to veterinary medicine,* ed 2, Philadelphia, 1991, JB Lippincott.

* *(),* Not reported in horses.

3.2.5

Approach to the Horse With Polyuria and Polydipsia

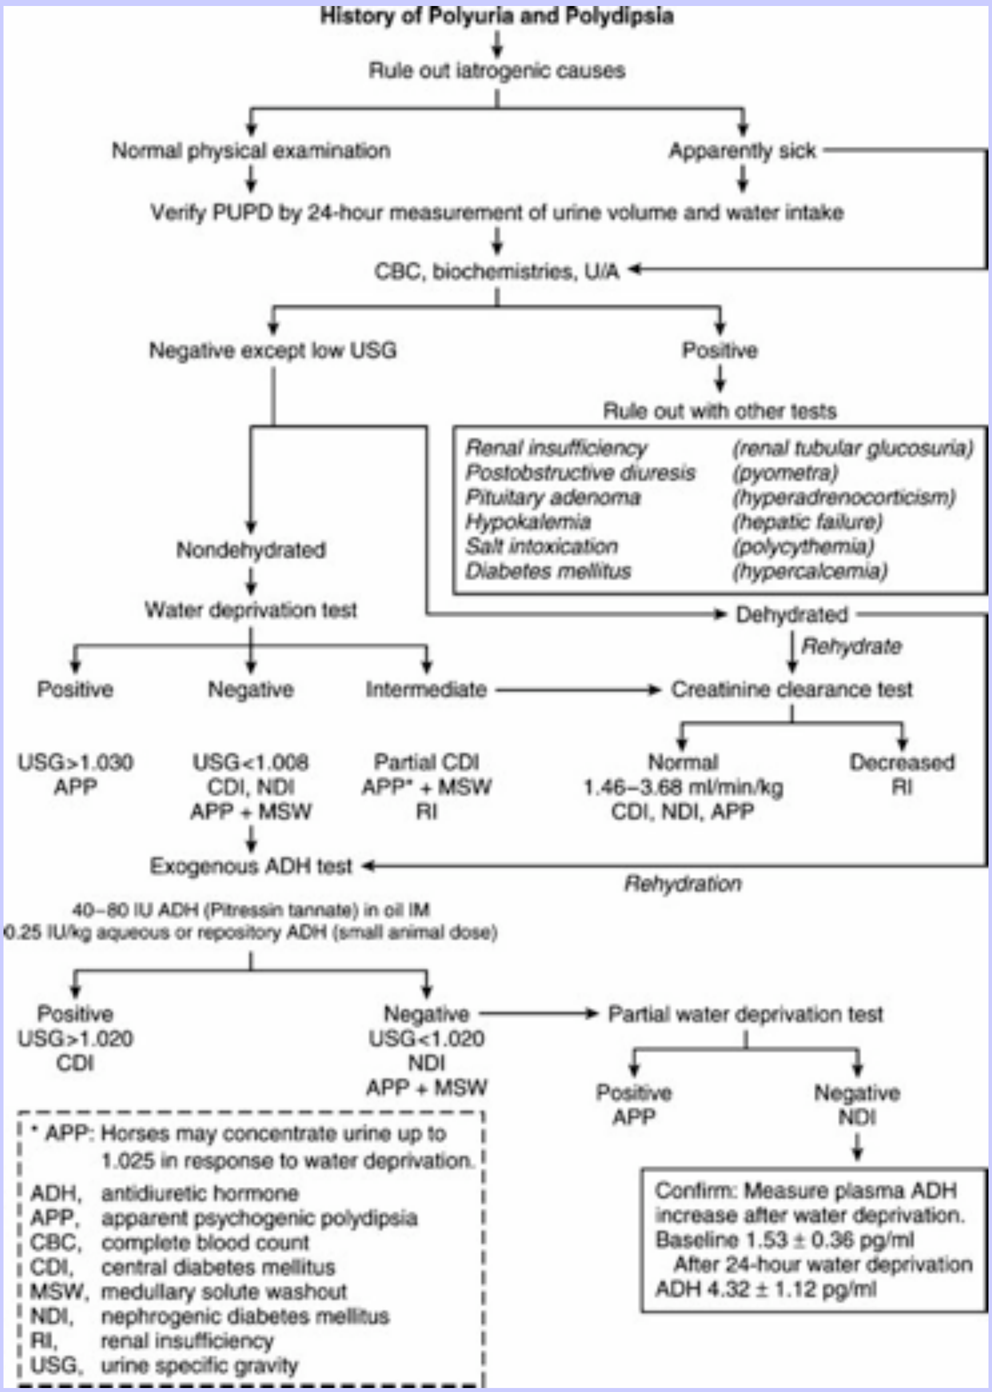
Iatrogenic causes of polyuria and polydipsia (see Box 3.2-1) should be ruled out by careful assessment of the history and by documentation of return to normal urine volume and water intake after withdrawal of intravenous fluids, excess dietary salt, or drugs implicated in causing polyuria and polydipsia (Figure 3.2-2). Verification of 24-hour urine volume and water intake should be undertaken for horses suspected of having polyuria and polydipsia that do not display obvious polyuria (frequent large volume urination and wet stall) and polydipsia (water bucket always empty and overt thirst). Hemogram, serum biochemistries, and urinalysis should be assessed for all horses with polyuria and polydipsia. A hallmark finding in horses with polyuria and polydipsia is a decreased urine specific gravity (USG). Identification of other abnormalities on laboratory tests (e.g., increased blood urea nitrogen or creatinine concentrations, hyperglycemia, and hypokalemia) necessitates ruling out the presence of underlying diseases (such as renal insufficiency and adenoma of the pars intermedia of the pituitary) using specialized laboratory tests.

The hydration status of horses then should be assessed carefully. Those horses that are dehydrated should be rehydrated judiciously with intravenous fluids, taking care not to overhydrate horses with renal insufficiency. After rehydration, when possible, creatinine clearance should be determined by using a urine collection

apparatus to allow 24-hour volumetric urine collection. A creatinine clearance value below the reference range (1.46 to 3.68 ml/min/kg)[28] suggests that renal insufficiency with decreased glomerular filtration rate and solute diuresis are likely present. A creatinine clearance within the reference range indicates that central diabetes insipidus (CDI), nephrogenic diabetes insipidus (NDI), or apparent psychogenic polydypsia (APP) is present. To distinguish among these differential diagnoses, an exogenous ADH challenge test should be performed (see the subsequent discussion).

Horses with polyuria and polydipsia that are well hydrated and healthy based on physical examination and
results of hemogram and serum biochemistry determinations should be subjected to a water deprivation test to 117
assess renal ability to conserve water.[2,29,30] Water deprivation testing is contraindicated in a dehydrated horse 118
with a low USG. Such horses have already undergone an endogenous water deprivation test (clinical dehydration is present) and have responded with an inappropriately low USG. The following guidelines for interpretation of water deprivation test results are based on practical experience and the limited data available. A positive response to water deprivation (USG >1.030) indicates that the horse has APP, whereas a negative response (USG <1.008) after 24 hours of water deprivation or greater than 5% weight loss[31] is consistent with a diagnosis of
CDI, true NDI, insensitivity of collecting duct receptors to ADH, or apparent psychogenic polydipsia and 118
medullary solute washout (APP plus MSW). Horses with a negative response to water deprivation testing should 119
undergo an exogenous ADH challenge. Some horses may have an intermediate response to water deprivation. An intermediate response is consistent with partial CDI or APP plus MSW or renal insufficiency, and assessment of creatinine clearance is indicated. Consult Chapter 18 for a more detailed discussion of water deprivation testing.

Figure 3.2-2 Approach to the polyuric patient. *PUPD,* Polyuria and polydipsia; *U/A,* Urinalysis. Modified from Hansen B: Polyuria and polydipsia. In Fenner WR: *Quick reference to veterinary medicine,* ed 2, Philadelphia, 1991, JB Lippincott.



An evaluation of a response to the administration of exogenous ADH is indicated for horses that do not concentrate their urine adequately during water deprivation testing, for horses that require rehydration and subsequently demonstrate creatinine clearance values within reference ranges, and for rehydrated horses for which creatinine clearance determinations are impractical. Two regimens for exogenous ADH administration have been reported: 40 to 80 IU ADH as Pitressin tannate in oil intramuscularly[32] or 0.25 IU/kg aqueous or repository ADH intramuscularly. A few reports of responses of horses to exogenous ADH administration have been made, and the following recommendations are based on clinical experience. A positive response to exogenous ADH (USG >1.020) confirms the diagnosis of CDI.A negative response (USG <1.020) implies that NDI or APP plus MSW is present.[31]

MSW may result in a decreased USG despite the presence of adequate ADH. A partial water deprivation test should result in an increase in USG in horses with APP plus MSW but should have no effect on horses with true NDI or insensitivity of collecting duct receptors to ADH. The horse is allowed to consume its normal diet and water ad libitum. Voluntary water consumption is monitored closely for 3 to 4 days to establish a baseline. Water available to the horse then is decreased by 5% to 10% of the baseline voluntary intake. Water should be offered in aliquots several times a day to prevent the horse from consuming most of the water in a short time. Water intake should never be restricted below maintenance requirements (about 40 ml/kg/day). During water restriction, the horse is allowed to eat its regular diet. The horse should be weighed daily if possible and should be observed carefully for signs of dehydration (prolonged capillary refill time, increasing heart rate, prolonged skin tenting, and hypernatremia). Moderate water restriction in the face of continued intake of dietary solutes facilitates reestablishment of the corticomedullary osmotic gradient.[15] Results of partial water deprivation tests in horses have been reported infrequently.

The diagnosis of true NDI or insensitivity of collecting duct receptors to ADH may be confirmed by measuring plasma ADH concentrations before and after partial water deprivation. ADH concentrations have been reported to increase from baseline values of 1.53 ± 0.36 pg/ml to 4.32 ± 1.12 pg/ml after 24 hours of water deprivation in ponies.[13]

Because CDI, NDI, and APP are uncommon in horses, the presenting complaint of polyuria and polydipsia usually signifies other underlying disease. The most likely underlying disease is renal insufficiency. Pituitary adenoma should be considered in horses with compatible clinical signs (hirsutism, weight loss, and laminitis) and supporting laboratory data (hyperglycemia and failure of suppression of cortisol production by dexamethasone).[33] Medullary washout may be a more common complication of primary diseases and their therapy in horses than has been reported to date. Potential causes of diuresis compatible with the case history and clinical signs should be investigated, and a partial water deprivation test should be considered when horses exhibit polyuria and polydipsia.

3.3

3.3—Edema

Kenneth W. Hinchcliff

Edema is the excessive and abnormal accumulation of fluid in the interstitium. Interstitial fluid accumulates because of imbalances in the rates with which fluid enters and exits the interstitium. Factors that increase the rate of fluid flux from the capillary or impair lymph drainage sufficiently to overwhelm normal compensatory mechanisms result in accumulation of fluid and the development of edema.

3.3.1

Physiology

The volume of interstitial fluid and lymph fluid in the normal horse is 8% to 10% of body mass,[1] or 36 to 45 L in a 450-kg horse. Interstitial fluid consists of water, protein, and electrolytes. Compared with plasma, interstitial fluid has a slightly lower concentration of cationic electrolytes, a slightly higher concentration of chloride, and a much lower concentration of protein (1.2 versus 0.2 mOsm/L of water).[2] The amount and function of plasma proteins within the interstitial space are not inconsequential. A constant circulation of plasma proteins occurs between the vascular and interstitial spaces, with about half of the protein circulating every 24 hours in human beings. More than half of the plasma protein content of the body is contained within the interstitial space at any one time. Plasma proteins within the interstitial space are important in the transport of water-insoluble substances from the vascular space and in resistance to infection.[3]

Interstitial fluid is contained within the interstitium, the intercellular connective tissues that lie between the cellular elements of the vascular and cellular compartments of the body. The extracellular tissue of the interstitium, except in the case of bone, consists of a three-dimensional collagen fiber network embedded in a proteoglycan gel matrix.[4] Interstitial water exists as free water and as water within the proteoglycan gel. Normally, only a small proportion of interstitial fluid exists as free water, most of the water being contained in

the interstitial gel. However, in edematous states, the proportion of fluid as free water within the interstitium increases.[2]

The source of interstitial fluid is the intravascular space. The volume of interstitial fluid is determined by the functional relationships of three major anatomic structures: the capillary, the interstitial space, and the lymphatics.[5] Functionally, the volume of fluid that accumulates in the interstitium is determined by the rate of ingress of fluid from the vascular space, the compliance of the interstitium, and the rate at which fluid is evacuated from the interstitium. The net rate of ingress of fluid from capillaries into the interstitium is determined by a number of factors acting across the capillary membrane, the effects of which are related by Starling's equation:

$$J = Kf[(P_c - P_t) - \sigma(\pi_p - \pi_t)]$$

in which J equals the volume flow across the capillary wall; Kf equals the filtration coefficient of the capillary wall (volume flow per unit time per 100 g of tissue per unit pressure); P_c equals capillary hydrostatic pressure; P_t equals interstitial fluid hydrostatic pressure; σ equals the osmotic reflection coefficient; π_p equals the colloid osmotic (oncotic) pressure of the plasma; and π_t equals the colloid osmotic (oncotic) pressure of the interstitial fluid.[6] Although all these factors act in concert to determine the rate of net fluid efflux from the capillary, considering them individually is conceptually easier.

120
121

3.3.1.1 FILTRATION (Kf) AND REFLECTION (σ) COEFFICIENTS

Together the filtration and reflection coefficients describe the properties of the capillary membrane that determine the ease with which water, protein, and other plasma constituents move from the vascular space to the interstitium. The filtration coefficient, which is the product of the hydraulic permeability and surface area of the capillary, is a measure of the ease with which water crosses the capillary membrane. The reflection coefficient is an indicator of the degree to which the capillary membrane resists the passage of a substance, such as protein. A reflection coefficient can be defined for each substance; a reflection coefficient of 0 indicates that the molecule crosses the membrane as readily as does water, whereas a value of 1 indicates that the membrane is impermeable to the substance. The reflection coefficient for a substance may vary with the anatomic site of the capillary[7,8]: Capillaries in the liver are permeable to albumin, whereas capillaries in muscle are much less permeable and cerebral capillaries are among the least permeable to albumin.

The movement of fluid and protein across the vascular membrane is assumed to be passive, with plasma water and protein exiting the vascular space through pores in the capillary membrane. However, the rate with which various plasma constituents cross the capillary membrane varies considerably depending on the constituent and the tissue. For example, muscle capillary pores are permeable to water molecules (reflection coefficient of 0) but much less permeable to albumin (reflection coefficient of approximately 0.9).[2] Movement of solutes across the endothelium is not understood fully, being complex, but is affected by the concentration of the solutes on either side of the membrane, solute charge and interaction with other solutes, and capillary pore configuration.[9]

Together the filtration and reflection coefficients partially determine the rate of fluid flux across the capillary wall, and the composition of the fluid. For a given hydrostatic and oncotic pressure difference, tissues with higher filtration coefficients (whether because of a larger capillary surface area or more porous capillaries) will have a greater fluid flux. Conversely, under the same circumstance, increases in the reflection coefficient of the capillary wall reduce fluid flux. The differential permeability of the capillary membrane to water and

protein has important consequences in the maintenance of the oncotic pressure difference between plasma and interstitial fluid.

3.3.1.2 HYDROSTATIC AND COLLOID OSMOTIC PRESSURES

Transcapillary fluid flow is results from an imbalance between the hydraulic forces favoring movement of water from the capillary into the interstitium and the forces favoring movement of water in the reverse direction. The forces contributing to fluid movement out of the capillary are the intracapillary hydrostatic pressure and the interstitial colloid osmotic pressure, whereas those forces favoring movement of fluid from the interstitium to the capillary are the interstitial hydrostatic pressure (if it is positive) and the plasma colloid osmotic pressure.[10]

The principal force favoring fluid efflux from the capillary is the hydrostatic pressure within the capillary. Capillary hydrostatic pressure varies among different tissues and decreases along the length of the capillary. Hydrostatic pressure within a capillary is determined by the arterial and venous pressures and by the precapillary and postcapillary resistances.[11] Specifically, capillary pressure is determined by the ratio of the postcapillary resistance (R_a) to the precapillary resistance (R_v), and the arterial (P_a) and venous (P_v) pressures:

$$P_c = \frac{(R_v/R_a)P_a + P_v}{1 + (R_v/R_a)}$$

Thus a small increase in venous pressure has a much greater effect on capillary pressure than does an increase in arterial pressure. For this reason the hydrostatic pressure is greater in capillaries below the heart (e.g., legs) than in those above the heart (e.g., head).

The colloid osmotic pressure of the plasma is the principal force minimizing fluid efflux from the capillary. The colloid osmotic pressure is generated because the plasma and interstitial fluid are separated by a semipermeable membrane—the endothelium—and vary slightly, but significantly, in composition. As noted previously, the interstitial fluid has a lower protein concentration than does plasma but has an essentially identical electrolyte concentration. The difference in protein concentration across the semipermeable endothelium generates an osmotic force that tends to draw water from the interstitium into the plasma.

In addition to the capillary hydrostatic pressure, the colloid osmotic pressure and negative hydrostatic pressure of the interstitial fluid favor fluid movement out of the capillary. Fluid flux across the capillary results from the summation of these forces (Table 3.3-1). These figures should be recognized as representing the forces at the midpoint of an idealized capillary and that the forces are dynamic, changing between tissues and even along the length of the capillary. In fact, a large net flux of fluid from the capillary occurs at its arteriolar end, 121
where capillary hydrostatic forces are greatest and plasma oncotic forces are least, and a net flux of fluid into 122
the capillary toward its venous end, where capillary hydrostatic forces are least and plasma oncotic pressure is greatest.

TABLE 3.3-1 Mean Forces (mm Hg) Influencing Fluid Movement Into or Out of the Capillary

HYDROSTATIC PRESSURES	
Mean capillary pressure	17.0
Interstitial pressure	–5.3
Total hydrostatic pressure favoring filtration	22.3
COLLOID ONCOTIC PRESSURES	
Plasma oncotic pressure	28.0
Interstitial oncotic pressure	6.0
Total oncotic pressure opposing filtration	22.0
TOTAL PRESSURE FAVORING FILTRATION	0.3

Data from Guyton AC: *Textbook of medical physiology,* ed 8, Philadelphia, 1986, WB Saunders.

The small imbalance in filtration forces results in a net efflux of fluid from the capillary into the interstitial tissue. This fluid does not accumulate in the interstitium; it is removed by the lymphatics.

3.3.1.3 LYMPHATICS

The lymphatics drain the interstitium of fluid and substances, notably proteins, that are not absorbed by the capillaries. The lymphatics represent the only means by which interstitial protein is returned to the circulation. Interstitial fluid, and with it protein, moves down a pressure gradient into lymphatic capillaries through clefts between the lymphatic endothelial cells. Lymphatic endothelial cells are supported, and the lymphatic capillaries maintained patent, by anchoring filaments that attach the endothelial cells to surrounding connective tissue. Lymphatic fluid progresses centripetally through progressively larger vessels before draining into the great veins of the chest. Lymphatic valves prevent the retrograde flow of fluid from the lymphatics. Lymph is propelled by factors extrinsic to the lymphatics, including muscle activity, active and passive motion, posture, respiration, and blood vessel pulsation. Exercise causes a significant increase in lymph flow, at least in part because of the increase in tissue pressure that is associated with muscle contraction, although passive motion also increases lymph flow. Standing results in significant diminution or cessation of lymph flow from, and the prompt accumulation of interstitial fluid in, the lower extremities of human beings. In addition to the extrinsic factors affecting lymph flow, coordinated contractions of lymphatic vessels contribute substantially to the centripetal flow of lymph.[12]

3.3.2 Mechanisms of Edema Formation

Simply stated, accumulation of excessive fluid in the interstitial spaces—edema—results from an imbalance of the rates of fluid filtration from the capillaries and drainage by the lymphatics. Perturbations of one or more of the forces that affect filtration across the capillary alter the rate at which fluid enters the interstitium. Increases in capillary hydrostatic pressure, decreases in plasma oncotic pressure, and increases in interstitial oncotic pressure all favor increased fluid filtration. Conversely, increased interstitial hydrostatic pressure and decreased interstitial oncotic pressure act to inhibit fluid filtration.

Box 3.3-1 lists the fundamental mechanisms of accumulation of excessive interstitial fluid. Increases in capillary hydrostatic pressure, which occur with venous obstruction or arteriolar dilation, such as that associated with inflammation, increase net fluid efflux. The edema that occurs with congestive heart failure likely has an increase in capillary hydrostatic pressure as one of its causes, although the mechanism is complex.[13] Posture also affects capillary hydrostatic pressure; capillaries below the level of the heart have higher hydrostatic pressures than do capillaries above the level of the heart.

A decrease in the oncotic gradient across the capillary endothelium, which occurs with a decreased plasma oncotic pressure or an increased interstitial oncotic pressure, results in an increase in efflux of fluid from the capillary. A decrease in plasma oncotic pressure decreases the oncotic gradient that favors movement of fluid into the capillary. Consequently, the capillary hydrostatic pressure, which favors filtration, predominates and fluid accumulates in the interstitium. Plasma oncotic pressure decreases when plasma protein concentration declines. Albumin is the plasma protein that exerts the preponderance of the oncotic force[8]; therefore clinically, edema often is associated with hypoalbuminemia. An increase in the permeability of the capillary membrane greatly increases fluid and protein transport into the interstitium and decreases the ability of the membrane to maintain a difference in oncotic pressure between the plasma and the interstitium.[5] Capillary permeability increases when the endothelium is damaged, such as by vasculitis or inflammatory reactions. 122 123

3.3.2.1 BOX 3.3-1 PATHOGENESIS OF EDEMA

3.3.2.1.1 Increased Capillary Hydrostatic Pressure

Venous obstruction

- Thrombophlebitis
  - Compression (mass, tourniquet)

Venous congestion

- Posture (dependent limbs)
- Congestive heart failure

Arteriolar dilation

- Inflammation
- Increased body water

3.3.2.1.2 Decreased Plasma Oncotic Pressure

Panhypoproteinemia

Hypoalbuminemia

3.3.2.1.3 Increased Interstitial Oncotic Pressure

Increased capillary permeability

3.3.2.1.4 Decreased Lymph Flow

Lymphatic obstruction

Lymphatic obstruction prevents the removal of interstitial fluid and protein. Filtration of fluid and passage of small amounts of protein into the interstitial space continues in the presence of lymphatic obstruction. The interstitial fluid is reabsorbed by the capillaries; however, the protein is not. Consequently, the protein content of the interstitial fluid gradually increases, with a resultant increase in interstitial oncotic pressure that favors filtration of fluid. The increased interstitial oncotic pressure causes fluid to accumulate in the interstitium, thus exacerbating the edema.[2]

Alterations in the magnitude of one or more of Starling's forces may be offset by compensatory changes in lymph flow and other of Starling's forces. In concert, Starling's forces and lymph flow act as “edema safety factors” to prevent the excess accumulation of interstitial fluid and development of frank edema. For example, lymph flow increases with the increased filtration associated with increased capillary hydrostatic pressure. Thus a larger volume of fluid enters and is removed from the interstitial space. The interstitial protein concentration decreases as increased fluid flow washes protein out of the interstitial space. Reduced interstitial space protein concentration increases the oncotic gradient, inhibiting fluid efflux from the capillary, and decreases the rate of movement of fluid from the capillary to the interstitial space.[6]

3.3.3 Diagnostic Approach to the Patient With Edema

Edema is not of itself a disease; rather it is a sign of a disease process. Therefore the diagnostic approach to the patient with edema is based on an understanding of the pathogenesis of edema and a knowledge of the diseases 123
likely to be involved (Box 3.3-2). The diagnostic approach to an animal with edema should not be any different 124
than for any other sign of disease. A clinical examination, including history and physical examination, permit the development of a list of potential diagnoses and dictate the appropriate subsequent steps in confirming the diagnosis. The reader is referred to those sections of the text that deal with specific diseases for a description of the appropriate diagnostic aids.

When taking the history of a horse that has edema, one should focus on acquiring those facts that have the greatest diagnostic use in differentiating among those diseases that have edema as a sign. One should consider the following aspects:

- Housing, season, and geographic region
- Vaccine and parasiticide administration
- Exposure to other horses and diseases present within the herd
- The duration of the edema, its distribution, and the presence of any other clinical signs

One should investigate the remainder of the history depending on the responses to initial questions.

The physical examination should begin with a visual evaluation of the attitude and physical condition of the horse. The temperature, pulse, and respiration should be recorded. Although the physical examination should be complete, particular attention should be paid to those body systems that the preliminary examination indicates may be involved in the disease process. The physical examination reveals the distribution and severity of edema. Edema that is localized to one extremity or is not bilaterally symmetric is more likely to be caused by local factors (e.g., lymphangitis or venous obstruction) than by systemic disease. Conversely, edema that involves several areas of the body and has a symmetric distribution is likely to be associated with systemic disease (e.g., the ventral edema of congestive heart failure).

Following the initial clinical examination, the clinician will have developed an ordered list of potential diagnoses. Confirmation, or elimination, of these diagnoses depends on subsequent diagnostic procedures, including the response to therapy. Sections of this text deal with the specific disease processes for appropriate diagnostic procedures.

3.4 3.4—Changes in Body Weight

Jonathan H. Foreman

An unwelcome or unexpected change in the body weight of a horse is a commonly encountered problem in equine practice. Although obesity may be a more common problem, weight loss often represents a more serious situation, with potentially severe consequences. Normal or acceptable body weight is also in the eye of the beholder, because a horse with a given body weight might look overweight as an endurance horse, appropriate as a Thoroughbred racehorse, or too thin as a show hunter.

Whether dealing with a problem of weight loss or weight gain, the veterinarian always should investigate the
feeding practices of the horse. Not uncommonly the owner reports that the horse is receiving 3 lb of grain twice 124
daily when the actual measuring device (usually the everyday coffee can) differs in net grain weight once the 125
volume of the measuring device and grain density are taken into account. Observing firsthand the feeding practices of the stable may be necessary to document that the horse actually is getting the reported amount of grain 2 or 3 times daily. Hay should be examined for type, quality (color, texture, leafiness, and steminess), mold, weeds, and potentially toxic plants. The horse in question should be observed eating hay and grain to ensure that it really does consume the amounts the owner or feeder reports.

The veterinarian also should observe nursing foals when they suckle. The udder should be examined before and after nursing to ensure that the mare actually is producing sufficient milk and that the foal actually is nursing the mare completely until her udder is empty. The milk itself should be examined from both halves of the udder to see that it appears grossly normal (no evidence of mastitis). The nostrils of the foal should be examined after nursing to determine the presence of milk reflux caused by dysphagia, esophageal obstruction, or gastric reflux associated with gastrointestinal ulcers.

3.4.1 Decreased Body Weight

Losses in body weight are usually insidious and chronic but may be surprisingly rapid in the face of acute overwhelming systemic infections (Box 3.4-1). Causes have been classified variously as gastrointestinal, nutritional, infectious, or hypoproteinemic.[1,2] Differential mechanisms include decreased feed intake, decreased absorption of nutrients, decreased nutrient utilization, and increased loss of energy or protein leading to a catabolic "sink."[1–3]

Decreased feed intake may be caused by management factors, poor dentition, dysphagia, or esophageal obstruction. Management factors leading to weight loss may be multifactorial and include inadequate amounts of feed, inadequate quality of feed, or inability of the horse to eat the proper amounts of the feed given. A horse with severe lameness (e.g., chronic laminitis) may not be able to ambulate to the feed source. A horse low on the pecking order in a pasture hierarchy may be unable to eat because it cannot approach the feed without the other horses bullying it and fending it away. The feed must be palatable and digestible. Appropriate amounts and types of concentrates must be fed considering the work schedule or pregnancy status of the horse. Proper investigation of stable feeding practices is described earlier.

Poor dentition may cause the horse not to eat some or all of its grain or hay. Parrot-mouthed horses or aged horses with receding incisor teeth (more than 25 years old) may have difficulty in tearing off grass when grazing. A horse with one or more oral sores from a poorly fitting bit or from sharp cheek teeth may exhibit partial or complete inappetence because of pain associated with chewing. Sharp cheek teeth, wave mouth, or step mouth may lead to poor digestion and incomplete absorption of nutrients because of inadequate mastication of hay leading to poor fiber use during the hindgut (cecum) fermentation process.

3.4.1.1 BOX 3.4-1 MECHANISMS AND DIFFERENTIAL DIAGNOSES FOR DECREASED BODY WEIGHT

3.4.1.1.1 Decreased Dietary Intake

Inadequate diet

Lameness

Pecking order

Poor dentition

Dysphagia

Esophageal obstruction

3.4.1.1.2

Maldigestion and Malabsorption

Lactose intolerance

Gastrointestinal ulceration

Parasitism

Diarrhea

Inflammatory intestinal disease

- Granulomatous enterocolitis
- Eosinophilic enterocolitis
- Lymphocytic/plasmacytic enterocolitis

Gastrointestinal neoplasia

3.4.1.1.3

Inappropriate Hepatic Utilization

Inadequate circulation and respiration

- Chronic obstructive pulmonary disease

3.4.1.1.4

Increased Rate of Protein and Energy Loss

Infection

- Pneumonia
- Pleuritis
- Peritonitis
- Equine infectious anemia

Protein-losing eneropathy

- Diarrhea

- Gastrointestinal ulceration
- Parasitism
- Inflammatory intestinal disease
- Gastrointestinal neoplasia

Renal disease (glomerular)

Increased metabolic energy use

- Chronic pain
- Secondary hyperadrenocorticism

Dysphagia has many causes, including abnormal prehension, chewing, or swallowing.[4] Abnormal prehension 125
can be caused by tongue lacerations; dental, mandibular, or maxillary fractures; damage to nerves supplying the 126
tongue or facial musculature (local trauma, equine protozoal myelitis, or polyneuritis equi); or central neurologic disease (equine protozoal myelitis). Basal ganglia lesions caused by poisoning by ingestion of yellow star thistle or Russian knapweed prevent normal prehension in the pharynx.[5] Swallowing abnormalities may be caused by neurologic (equine protozoal myelitis, viral encephalitis, or guttural pouch infection), muscular, or physical obstructions such as strangles, abscesses, or guttural pouch distention.[4] Muscular causes include hyperkalemic periodic paralysis in Quarter Horse foals, vitamin E or selenium deficiency in neonates, botulism in neonates and adults, and local trauma subsequent to laryngeal surgery (laryngoplasty).

Esophageal obstruction usually presents acutely because an apparently dysphagic horse regurgitates food from its nostrils while attempting to eat or drink. Chronic choke, or anorexia related to painful swallowing caused by partial esophageal obstruction may lead to weight loss without the owner realizing that the horse is not eating adequately. Esophageal endoscopy is usually diagnostic, but positive contrast radiography may be helpful and is sometimes necessary to establish an accurate diagnosis.

If the horse with weight loss has been observed fully to ingest adequate amounts of good-quality hay and grain, then decreased feed absorption must be considered the reason for weight loss. Maldigestion and malabsorption are not easily confirmed diagnoses, but tests based on luminal absorption of simple sugars (xylose or glucose tolerance tests) have been used to document malabsorption syndromes.[3,6,7] These tests are described in greater detail in Chapter 13.4. Malabsorption may be caused by parasitism, diarrhea, and inflammatory or neoplastic intestinal disease.

Gastrointestinal parasitism results in weight loss because of several mechanisms.[2] Parasites may compete directly for nutrients within the lumen of the bowel. Malabsorption may result from a lack of mucosal integrity, a decrease in intestinal villi size and number (and subsequent decrease in mucosal absorptive surface area), and a decrease in digestive enzymes that originate in the mucosa. Competition of parasites for protein sources may

result in decreased availability of amino acids for production of digestive enzymes or mucosal transport proteins. Increased mucosal permeability caused by leakiness in mucosal intercellular bridges may result in mucosal edema and increased transudation of intercellular fluid and its associated electrolytes, amino acids, and sugars into the lumen of the intestine.

Chronic diarrhea results in partial or complete anorexia, which contributes directly to weight loss. More rapid (decreased) gastrointestinal transit time results in increased losses of incompletely digested dietary feedstuffs. Malabsorption may result from decreased transit time and from villus blunting caused by specific pathogens, such as in viral diarrhea (see Chapter 13.4). Bacterial pathogens may compete directly for luminal nutrients. Mucosal invasion by viral and bacterial pathogens may cause mild to severe degrees of mucosal sloughing (ulcers), which result in maldigestion, malabsorption, and increased mucosal losses of intercellular fluid (e.g., in parasitism).

Given that the horse has adequate feed intake and absorption, inappropriate hepatic use of amino acids and sugars must be considered as a differential diagnosis for weight loss. Chronic liver disease may result in weight loss because of inappetance, maldigestion (caused by inadequate bile acid production), and inadequate or improper processing of amino acids into normal plasma proteins in the liver. These abnormalities may result in lowered concentrations of serum albumin, liver-dependent clotting factors (factors II, VII, IX, and X), and total plasma or serum protein. Lowered circulating proteins (especially albumin) may result in decreased plasma colloid osmotic pressure and thus may manifest as peripheral dependent edema in the distal limbs, pectoral region, and ventral midline. This peripheral edema may mask further weight loss by making the torso of the horse appear to be heavier than it actually is. Decreases in clotting factors may result in bleeding diatheses. Hyperlipemia, hyperlipidemia, fatty liver syndrome, and ketosis may be seen in poorly fed ponies and in miniature horses with acute anorexia or overwhelming energy demands, such as pregnancy or lactation.[8]

Increased loss of protein or energy is a common cause of decreased body weight in horses. Luminal losses of fluid, electrolytes, and nutrients were described earlier for intestinal parasitism and diarrhea. Acute inflammatory protein losses may occur into major body cavities in overwhelming infections such as pleuritis or peritonitis. Chronic abscessing pneumonia, pleuritis, and peritonitis often result in increased, rather than acutely decreased, serum total protein because of increased γ-globulin production in response to chronic antigenic stimulation from the chronic infection. These chronic infections also usually have weight loss as an additional clinical sign because of the continuing catabolic processes associated with the infection itself. Equine infectious anemia is a type of persistent systemic infection that in its symptomatic form may result in chronic weight loss and varying levels of anemia.[9] Asymptomatic equine infectious anemia carriers may have no weight loss or other obvious clinical signs but can infect pasture mates via vector transmission.

Protein-losing enteropathy is not a definitive diagnosis but rather is a group of diseases, each of which results in luminal losses of fluid, electrolytes, plasma proteins, and nutrients. Mechanisms of protein and fluid loss were described earlier for intestinal parasitism and diarrhea. Gastrointestinal ulcers have been reported to result in lowered serum total protein and weight loss.[10] One of the early indications of nonsteroidal antiinflammatory drug toxicity is detection of a lowered serum total protein. Horses with such a condition also may manifest varying degrees of inappetence and colic, especially associated with the immediate postprandial period. Intestinal neoplasms (usually lymphosarcoma) often manifest as a protein-losing enteropathy with weight loss.[11]

126
127

Acute or chronic renal diseases, especially involving glomerulonephritis, can result in urinary protein loss and subsequent body weight loss.[12] Horses with this condition may have polyuria and polydipsia as associated clinical signs. Owners or handlers often report polyuria as increased wetness in stall bedding. The veterinarian should question owners thoroughly regarding the water intake of the horse. The veterinarian may need to observe

stable watering habits, often including actually measuring the volume of the water buckets to establish definitively the presence of polydipsia. Turning off automatic waterers in the stall or pasture and offering the horse measured volumes of water from additional buckets may be necessary to establish a diagnosis of polydipsia. Urine puddles in stalls or collected urine samples may foam excessively because of increased protein concentrations. Increased urinary protein concentrations can be diagnosed quickly on the farm with the proper interpretation of urine dipstick protein indicators.

Neoplasms or abscesses within the thorax or abdomen serve as catabolic energy and protein sinks, resulting in chronic weight loss.[11–13] Chronic pain, such as that associated with severe, unresponsive laminitis, results in increased catabolism and weight loss, probably because of chronically elevated systemic catecholamine levels. Increased circulating epinephrine and norepinephrine levels result in a whole-body catabolic state with increased breakdown of stored energy sources and ultimately result in chronic weight loss. Similar weight loss caused by systemic catabolism can result from chronically elevated serum cortisol associated with pituitary adenoma and secondary hyperadrenocorticism.

Heart murmurs and resultant heart failure can cause weight loss because of inefficiency of circulation of nutrients and oxygen to peripheral tissues. Chronic obstructive pulmonary disease or heaves may result in weight loss because of an increase in the work of breathing and poor oxygenation of peripheral tissues. Although ventral abdominal musculature may hypertrophy and result in a heave line, weight loss is manifested by increased depth between the ribs and decreased muscular thickness and definition along the dorsal midline. Suckling foals with severe pneumonia may manifest weight loss if they become inappetent because of decreased suckling related to their severe dyspnea.

An appropriately taken history should document the type, amount, and quality of feed and hay being provided daily. Documentation of deworming products used and intervals of administration is critical. The history also may document the presence of anorexia, depression, polyuria, polydipsia, diarrhea, or other important historical signs that may point more quickly toward a specific cause of the weight loss.

The physical examination should reveal the presence of weight loss, a cardiac murmur, pneumonia or pleuropneumonia (increased lung sounds), chronic obstructive pulmonary disease (increased abnormal expiratory lung sounds), dental abnormalities, peripheral edema, urine staining on the hindlimbs, diarrhea, icterus, nasal discharge (dysphagia, pneumonia), fever, or hirsutism (secondary hyperadrenocorticism). The rectal examination may document the presence of intraabdominal masses (abscesses or neoplasms), enlarged left kidney, thickened intestinal or rectal wall, colonic displacement, gritty peritoneal surfaces (peritonitis), gritty feces (sand impaction), or diarrhea.

Fecal flotation may serve as an adequate screening tool to determine whether any evidence of parasitism exists. In the event of a positive fecal flotation, Baermann sedimentation may be necessary to determine quantitatively the severity of the patent parasitic load in the horse with weight loss. Fecal occult blood may be positive with gastrointestinal ulceration or neoplasms, but parasites or a recent rectal examination also may result in positive results.

Routine hematologic testing (complete blood count and fibrinogen) should assist in diagnosing infectious conditions such as pleuritis or peritonitis. Decreased serum or plasma total protein and albumin concentrations are evidence of hypoproteinemia and make the following conditions more likely: severe malnutrition, protein-losing enteropathy (diarrhea, parasitism, ulceration, intestinal neoplasms, or inflammatory intestinal disease), glomerular disease, acute pleuritis or peritonitis, or chronic liver disease. Increased total protein concentrations, especially γ-globulins, make chronic closed-cavity infections such as abscesses, peritonitis, or pleuritis more likely. Increased β-globulin fractions suggest the presence of parasitism.

Routine serum biochemistries should aid in diagnosing renal (renal azotemia, electrolyte abnormalities) and liver disease (increased γ-glutamyltransferase, aspartate aminotransferase, serum alkaline phosphatase, and lactate dehydrogenase). Urinalysis should reveal increased protein levels on dipstick or quantitative analysis in the event of glomerular protein losses. Metabolic alkalosis may be evident in the aftermath of salivary bicarbonate losses caused by dysphagia or esophageal obstruction. 127

128

Endoscopy may aid in diagnosing causes of dysphagia or esophageal obstruction. Lengthy endoscopes are necessary for examination of large adult horses for suspected gastrointestinal ulcers, but shorter endoscopes may suffice for foals or shorter-necked adults (e.g., Arabians and ponies).

Peritoneal fluid analysis documents the presence of a transudate (equivocal infection) or exudate (probable infection).[14,15] Aerobic and anaerobic peritoneal fluid cultures should be performed if intraabdominal infection is suspected. Exfoliative cytologic examination rarely may document the presence of neoplastic cells from intraabdominal neoplasms.[11–16]

Nonroutine tests should be performed only as indicated and should include oral absorption tests (see Chapter 13.4) and biopsies of the liver, kidney, or intestinal wall. Abdominal or thoracic ultrasonography should help to rule out abnormalities of the liver or kidneys and may document the presence of abnormal fluid (peritonitis or pleuritis) or masses (abscesses or neoplasms). Cardiac ultrasound should be definitive in the event of a murmur and suspected heart failure. Radiography also may be helpful to document the presence of thoracic masses or chronic obstructive pulmonary disease, but increased pleural fluid obscures visualization of other intrathoracic structures.

3.4.2 Increased Body Weight

Overfeeding may be the most common cause of obesity in horses and also may be the easiest to correct. The veterinarian should investigate the feeding practices of the stable and feed and hay sources thoroughly. Novice horse owners, single horse owners, and pony owners commonly overfeed their animals.

Ponies seem to be particularly susceptible to obesity, perhaps because their size renders them more easily overfed. However, at least one author has proposed that this tendency toward obesity in ponies receiving modern confinement diets may be because of their having evolved in the inhospitable ice age climates of northern Europe.[17] In that era, the lack of readily available grazing feedstuffs might have placed greater selection pressure on survival of ponies with more efficient dentition and better nutrient and fluid absorption from the gastrointestinal tract. The author argues that those ponies that had greater feed conversion efficiency would have been stronger, had longer lives, and been more available for breeding. Current illustrations of this theory may lie in the Welsh and Connemara pony breeds that still thrive and flourish in the wild in the inhospitable north Atlantic climates of the western coasts of Wales and Ireland, respectively.

Pregnancy in mares is a normal physiologic event that leads to increased body weight. Surprisingly, many new owners of mares may not know that their new purchase is pregnant. For an earlier negative pregnancy diagnosis to have been in error is not uncommon. Any mare that is gaining weight in an unexpected manner should be examined rectally, and by ultrasonography if necessary, for a possible pregnancy.

Hypothyroidism has been reported to be associated with weight gain and failure to become pregnant in broodmares.[18] Evidence for hypothyroid-associated weight gain and infertility was lacking in surgically created hypothyroid pony[19] and Quarter Horse[20] subjects. An abundance of field experience exists, however, from

which to infer a relationship between obesity, hypothyroidism, and infertility in mares.[17] Documentation of hypothyroidism must be by performance of a thyroid-stimulating hormone or thyroid-releasing hormone stimulation test,[21,22] because resting thyroid levels vary diurnally[23] and do not truly reflect thyroid function. One must also remember that only 5 days of normal phenylbutazone therapy results in abnormally low resting serum thyroid levels because of direct competition of phenylbutazone with thyroid hormone for serum protein-binding sites.[21] The diagnosis and treatment of hypothyroidism is described in greater detail elsewhere in this text.

Differential diagnoses for increased body weight include overfeeding, pregnancy, hypothyroidism, and other conditions that result in abdominal distention, such as bloat, ascites, uroperitoneum, fetal hydrops, and rupture of the prepubic tendon or abdominal wall musculature. The latter conditions are described in greater detail in Chapter 16.

Feeding practices should be investigated and observed firsthand if necessary. A positive pregnancy status should be an easy historical and rectal diagnosis. Most hematologic and biochemical tests are normal in the pregnant or simply overweight horse. Thyroid status should be assessed appropriately, not by simple resting thyroid hormone concentrations, but by thyroid-stimulating hormone or thyroid-releasing hormone stimulation tests that have been described previously and that are presented elsewhere in this text.[21,22]

Education of the client is important regarding feeding practices, especially if the overweight horse is determined simply to have been overfed by a novice owner. Dangerous consequences, including colic and laminitis, should be explained to the client.

3.5

3.5—Abdominal Distention

Jonathan H. Foreman

Increases in body weight because of overeating or pregnancy must be distinguished from increases in body girth caused by bloat, ascites, uroperitoneum, fetal hydrops, or ruptured prepubic tendon. In each of these conditions, body weight actually may increase because of fetal growth or fluid accumulation. More important, however, a perceptible change in the shape of the abdomen of the horse occurs.

Bloat usually is associated with colic signs in horses and is caused by gaseous intestinal distention resulting from ileus or simple obstruction of the large, or rarely small, intestine. Ileus caused by diarrhea, peritonitis, colic surgery, or parasympatholytic agents (e.g., atropine) can result in sufficient accumulation of intraluminal gas to be manifested as tympany, bloat, and mild to severe abdominal pain.[1] If optic topical atropine application is overly aggressive, secondary ileus and bloat may result. Rapid and severe gas production may follow grain overload; cecal and colonic fermentation of readily available carbohydrate sources results in rapid-onset colonic tympany and abdominal distention.[2] Exhaustion in endurance horses also is associated with intestinal shutdown and subsequent abdominal distention.[3] In any of these bloat conditions, abdominal auscultation in the flank area reveals decreased

or absent intestinal motility sounds (borborygmi) and perhaps increased gaseous distention sounds (pinging). Decreased borborygmi in the right flank are specific for cecal ileus.

Simple colonic obstruction also results in tympany and bloat. Strangulating obstruction results in greater pain than usually is manifested in simple obstruction and bloat. Colonic displacements are more common in older postpartum mares.[4] These horses often initially show mild colic signs and progressively develop more dramatic pain and abdominal distention. Miniature horses with simple obstructions caused by fecoliths often have bloat as the initial clinical sign.[5] Such cases have the additional complication that rectal examination may be impossible for differentiation of the source of the bloat. Even in full-sized horses, rectal examination may reveal that the abdomen is so filled with distended colon that the examiner can push an arm into the rectum no farther than wrist-deep. Colonic or cecal bloat can be relieved by trocarization through the flank, but relief is merely palliative and is usually temporary because the cause of the obstruction still has not been resolved.

129

130

Ascites does not occur commonly in horses and usually is caused by peritonitis or abdominal neoplasms. Peritonitis is caused by septicemia, laparotomy, intestinal leakage, internal abscess, or a penetrating external wound resulting in inflammation and usually infection of the peritoneal lining of the abdomen. Such inflammation results in increased fluid production by the squamous abdominal epithelium. Initially, this increased abdominal fluid may be characterized as a transudate (low cell count and low total protein). If inflammation with infection persists, the character of the fluid may change to that of an exudate (increased cell count >5000 nucleated cells/μl, increased neutrophil count, increased degenerate neutrophils, microscopically visible bacteria, and increased total protein).[6,7] These increases in abdominal fluid volume can be substantive and can result in abdominal distention that eventually becomes clinically apparent. Fluid ballottement in the equine abdomen is not an easily performed diagnostic technique but may be easier in foals, ponies, or miniature horses than in full-sized horses.

Ascites also may result from abdominal neoplasms. Tumors reported to cause ascites and weight loss in horses include lymphosarcoma, squamous cell carcinoma, mammary adenocarcinoma, and mesothelioma.[8,9] Although rare, mesothelioma may cause the most fluid production, because it is a tumor of the fluid-producing cells of the peritoneal lining. Mesothelioma may result in the production of large volumes of fluid (several liters) in a short time (24 hours) after a similarly large volume is drained from the same horse via abdominal catheterization or trocarization.

Ascites also may result from any condition that produces lowered serum total protein and albumin. With lowered intravascular colloid osmotic pressure, fluid diffuses or moves from the vasculature and results in dependent peripheral edema. Fluid also may accumulate within the major body cavities (i.e., the thorax and the abdomen).[7] The mechanisms for such low-protein conditions include poor protein intake, malabsorption, poor hepatic utilization, and increased rate of protein loss such as in glomerular renal disease, peritonitis/pleuritis, or gastrointestinal transudation (diarrhea or ulceration). Causes of peripheral edema are described elsewhere in this text.

Increased preload because of right ventricular heart failure also can result in a transudate fluid accumulation within the abdomen.[7] A horse with right ventricular heart failure usually has tricuspid insufficiency and manifests other signs of right ventricular heart failure, such as a murmur, exercise intolerance, jugular pulse, and edema of the ventral abdomen, pectoral muscles, and distal limbs. Severe mitral insufficiency also can result in right ventricular heart failure, but only after the development of left ventricular heart failure and its associated pulmonary edema, which is manifested by exercise intolerance, coughing, epistaxis, and increased respiratory effort.

Uroperitoneum results from leakage of urine from some part of the urinary tract into the abdomen and most commonly is associated with a ruptured bladder in neonatal foals (usually male). Uroperitoneum also may result

from a necrotic bladder caused by neonatal sepsis and urachal abscesses. Such foals often have pendulous, bloated abdomens that ballotte more easily than do the abdomens of adult horses with accumulation of fluid. Abdominal fluid actually may smell like urine, and peritoneal fluid creatinine concentrations will be high—often more than twice those of peripheral blood.[10–12] Because most classically described neonatal urinary bladder tears are dorsal near the trigone, the foal still may be able to produce a stream of urine despite having a leaking bladder. A ruptured urinary bladder abscess should be suspected in a foal with sepsis that initially responds to therapy for sepsis and then, several days later, has acute-onset depression, anorexia, ileus, and abdominal distention. Adults horses rarely have uroperitoneum; however, uroperitoneum has been associated with ruptured urinary bladders during stressful parturition in mares that manifest mild postpartum abdominal pain and abdominal distention.[12,13]

Fetal hydrops results from an accumulation of excessive amounts of fluid within the amnion (hydrops amnion) or chorioallantois (hydrops allantois).[14] Hydrops results in a bilaterally pendulous abdomen in a late-term pregnant mare. A rapid accumulation of fluid over 10 to 14 days may makes walking or perhaps even breathing difficult for the mare. A diagnosis may be made after taking history and performing a rectal examination, although palpating the fetus is usually difficult because the excess fluid causes the uterus to descend out of reach of the examiner. If necessary, a percutaneous ultrasonographic examination may be used to confirm the diagnosis by documenting the presence of increased intrauterine fluid within the fetal membranes.

A ruptured prepubic tendon results in a unilateral lowering of the abdominal margin and apparent distention of the abdomen only on the affected side. The condition is associated routinely with later-term pregnancy in mares and is thought to occur simply because of the increased weight of the pregnant uterus pressing downward on the abdominal wall. Rupture of the rectus, transverse, or oblique abdominal muscles also can result in ventral dropping or herniation of the abdomen late in gestation.[14] Ruptures may be more common in older or more sedentary mares, probably because of decreased abdominal wall strength and tone. Other than a focal abdominal wall hernia, a unilateral prepubic tendon rupture results in the only form of prominent unilateral abdominal distention in horses. Mares with ruptured prepubic tendons may have elicitable pain in the local abdominal wall and may demonstrate a 130
reluctance to walk. They may need assistance during parturition, because they may have difficulty performing an 131
effective abdominal press to aid in fetal expulsion.

Pregnancy, diarrhea, colic signs, colic surgery, and the use of parasympatholytic agents should be evident from the history. The rate of onset of abdominal distention may help to distinguish more acute conditions (e.g., gastrointestinal bloat from grain overload) from more chronic conditions (e.g., ascites caused by heart or liver failure). Signalment and history may assist in indicating specific conditions. A depressed, 48- to 72-hour-old male foal with fluid abdominal distention may be a likely candidate to have a ruptured urinary bladder and uroperitoneum. Miniature horses with bloat and colic signs frequently have simple obstructions owing to fecoliths or enteroliths.

A complete physical examination reveals the presence of a murmur that may be associated with heart failure and ascites. Other signs of heart failure also may be evident on physical examination. An actual defect in the integrity of the abdominal wall may be palpable on external examination of the abdomen in a mare with a ruptured prepubic tendon or ruptured abdominal wall musculature.[14] The veterinarian should attempt ballottement to discern the presence of increased free abdominal fluid in suspected ascites or uroperitoneum. Fever may indicate the presence of an infectious peritonitis or umbilical abscess.

A rectal examination is a critical part of examining a horse with bloat or colic but may be difficult to accomplish if colonic distention is dramatic or if the patient is small (i.e., a foal, pony, or miniature horse). A rectal examination further may document advanced pregnancy, resulting in mild bilateral abdominal distention (normal pregnancy), abnormal or severe bilateral distention (hydrops or bilateral ruptured prepubic tendon), or unilateral distention

(unilateral ruptured prepubic tendon or focal abdominal wall hernia). A rectal examination also may reveal abnormalities of the urinary tract (enlarged kidney or ureter, abscess, or neoplasm), which may result in uroperitoneum in adults.

An ultrasonographic examination may be helpful and is sometimes necessary to examine the distended abdomen and fetus in a pregnant mare. Such an examination must be performed percutaneously in late gestation. Ultrasonography can determine the location of increased abdominal fluid (intrauterine or extrauterine) and the health status of the fetus. Percutaneous placement of base-apex electrocardiographic leads across the abdomen of the mare may help to document that the fetus is still viable if an ultrasound examination does not produce definitive evidence (heart movement or gross fetal movement).[15]

Cardiac ultrasonography may help to document the presence of a cardiac valvular defect that can be the cause of ascites in a horse with heart failure. Abdominal radiography may assist in the diagnosis of abdominal distention caused by intestinal obstruction in a foal or miniature horse. Percutaneous ultrasound examination also may assist in documenting the source of abdominal distention (e.g., intussusception) in smaller horses or foals[16,17] and in characterizing umbilical and urachal abnormalities.[17]

Complete blood counts and plasma fibrinogen concentrations assist in diagnosing inflammatory conditions such as infectious peritonitis. Urachal or urinary bladder abscesses also may be associated with inflammatory leukograms. Blood or peritoneal fluid cultures may assist in documenting the offending bacterial agent(s). Foals or adults with uroperitoneum have elevated serum urea nitrogen, creatinine, and potassium and decreased serum sodium, chloride, and bicarbonate concentrations.[10,11]

Abdominocentesis should be attempted to distinguish the cause of ascites. Care must be taken, however, in obtaining peritoneal fluid from late-term pregnant mares to avoid penetrating directly into the distended uterus. Analysis of peritoneal fluid reveals abdominal fluid to be a transudate (equivocal infection) or exudate (probable infection).[6,7] Fluid should be cultured aerobically and anaerobically when infectious peritonitis is suspected. Exfoliative cytologic examination rarely may document the presence of neoplastic cells.[8,9] Peritoneal fluid creatinine concentration approaches or often exceeds (more than twice) that of serum if uroperitoneum is present.[10,11] Serum and peritoneal urea nitrogen concentrations are less reliable for such a diagnosis because the peritoneal membrane does not differentially sequester urea nitrogen (but does creatinine) within the abdominal cavity.

3.6

3.6—Dysphagia

Laurie A. Beard

3.6.1

Normal Eating

Normal eating is complex and requires normal anatomic structures and neurologic function. The process of eating can be divided into prehension (uptake of food into the oral cavity) and deglutition (transport of food from the oral cavity to the stomach). Prehension requires the lips to grasp and the incisors to tear the food.[1] Motor innervation to the tongue, lips, and muscles of mastication is provided by the hypoglossal, facial, and trigeminal nerves. Sensory input is important for successful prehension and requires intact olfactory, optic, and trigeminal nerves, providing smell, sight, and sensation of the rostral oral mucosa and lips. Normal prehension depends on the central nervous system to coordinate movements of the tongue and lips.

Deglutition involves mastication, swallowing, and transport of food through the esophagus to the stomach. Mastication or chewing of food initiates mechanical digestion and insalivation. Mastication is specifically a function of the molars to grind feed and the tongue and buccal muscles to position the food. The facial nerve provides motor and sensory fibers to the tongue and pharynx. The glossopharyngeal nerve provides sensory fibers to the caudal third of the tongue. The trigeminal nerve is sensory to the teeth and provides the important parasympathetic fibers to the parotid salivary gland. Function of this gland is critical to help liquefy food and provides a small amount of digestive enzymes.

Swallowing is complex and is performed in a series of steps. Initially, food must be moved to the base of the tongue and formed into a bolus. This action requires coordinated movements of the tongue and pharynx. Second, the bolus is forced caudally. As this action takes place, the oropharynx relaxes and the soft palate elevates to seal the palatopharyngeal arch and nasopharynx.[1] Next, the bolus enters the oropharynx and the hyoid apparatus swings rostrodorsally, which draws the larynx and the common pharynx forward.[1,2] The epiglottis is tipped caudally and prevents the bolus from entering the larynx. Finally, the bolus is moved into the common pharynx with pharyngeal muscle contractions and enters the open cranial esophageal sphincter. The sphincter closes to prevent esophagopharyngeal reflux and aerophagia. Herbivores are unique, because breathing continues uninterrupted during swallowing, unlike other animals.[1] The glossopharyngeal, vagus, and spinal accessory nerves provide sensory and motor fibers to the pharynx, larynx, and soft palate.

The esophageal phase of eating involves the transport of the food bolus to the stomach, with primary peristaltic waves, which are generated by continuous contraction of the pharyngeal peristalsis. The bolus is transported to the caudal esophageal sphincter, which relaxes to allow the bolus to enter the stomach and then contracts to prevent gastroesophageal reflux. If reflux does occur, esophageal clearance is achieved by secondary peristaltic waves. Antiperistalsis is normal in ruminants during eructation and regurgitation but is not normal in horses.[1]

3.6.2 Dysphagia

Dysphagia is defined as difficulty in swallowing but often is used to describe problems with eating.[2] Problems with eating may include problems with prehension, mastication, swallowing, and esophageal transport. In this section, the term *dysphagia* is used in the broader sense to describe problems with eating. Dysphagia can result from a number of disorders affecting any part of the upper gastrointestinal system (oral cavity, pharynx, and esophagus). Clinical signs of dysphagia vary depending on the cause and the location of the problem but may include ptyalism (excessive salivation), gagging, dropping food, nasal discharge, and coughing. Dysphagia can result from morphologic or functional disorders. The causes of these diseases may be acquired or congenital. Morphologic causes of dysphagia include abnormal anatomy, obstruction of the upper gastrointestinal tract, inflammation, and pain. Examples of anatomic abnormalities include a cleft palate and subepiglottic cysts.[3,4] Obstruction of the upper gastrointestinal tract most commonly includes feed impactions of the esophagus but also can include pharyngeal obstructions secondary to retropharyngeal lymph node masses or severe guttural pouch tympany.[5–10] Inflammatory conditions resulting in pain and dysphagia include periodontal diseases, foreign bodies, pharyngitis, epiglottitis, and mandibular or maxillary fractures.[3,6]

Functional disorders resulting in dysphagia include neurologic, neuromuscular, and muscular diseases. Functional disorders frequently result in problems with swallowing but less commonly involve mastication and prehension and rarely occur with esophageal transport. Neurologic diseases resulting in dysphagia may be peripheral or central. Peripheral neurologic problems frequently result from abnormalities of the guttural pouch but also can include toxic peripheral neuropathies, such as lead toxicity. Problems of the guttural pouch include infection (tympany, empyema, or mycosis), iatrogenic problems (infusion of caustic substances), and trauma (rupture of the longus capitis muscle from the basisphenoid bone and hemorrhage into the guttural pouch).[2,11,12] Central neurologic diseases may result in problems in prehension, mastication, or swallowing. Specific examples include equine protozoal myelitis, viral encephalitis (rabies and eastern and western encephalitis), toxic neuropathies (leukoencephalomalacia and nigropallidal encephalomalacia), and cerebral trauma.[1,2,7,13–15] Neuromuscular problems resulting in dysphagia generally present as a systemic disease and include diseases

such as botulism and organophosphate toxicity.[1,2,16,17] Muscular diseases resulting in dysphagia are rare but include nutritional muscular dystrophy (white muscle disease) in foals.[18]

3.6.2.1 BASIC APPROACH TO DYSPHAGIA

The initial evaluation of dysphagia focuses on determining whether morphologic or functional abnormalities exist. To answer these questions best, a thorough history, physical examination (including observation of the horse eating), and additional tests (e.g., endoscopic examination and radiographs) are required. A history of an acute onset of dysphagia is often consistent with trauma, whereas a slow progressive onset of clinical signs is more consistent with a neurologic problem such as guttural pouch mycosis, equine protozoal myelitis, or toxicities. The clinician should assess exposure of the horse to toxic substances or plants (lead or yellow star thistle). A history of treatment before the onset of dysphagia suggests trauma or injury to the pharynx. Use of a balling gun or flushing of guttural pouches may result in iatrogenic injury to the pharynx, esophagus, and guttural pouches. The clinician should determine concurrent problems in other horses (e.g., strangles or other bacterial infections of the submandibular lymph nodes).

In performing the physical examination, the clinician should pay close attention to the head and neck. Because rabies is a potential cause of dysphagia, protective measures while performing a careful and thorough physical examination are necessary. Ideally, all clinicians working on horses should have an adequate rabies antibody titer. An examination of the oral cavity is best accomplished with a mouth speculum, good light, and if necessary, the administration of sedation. The teeth should be examined carefully for retained deciduous caps, sharp points or hooks, wave mouth or step mouth, dental fractures, or patent infundibula.[3] Foreign bodies may become wedged between the molars or under the tongue. The tongue should be examined for lacerations, foreign bodies, and evidence of neoplasia. The throat latch area and neck should be examined for heat or swelling, which might be caused by a ruptured esophagus. The lungs should be auscultated carefully to determine if the horse shows evidence of aspiration pneumonia resulting from dysphagia.

A valuable activity is to watch the horse eat. The distinction between dysphagia and anorexia is important. Dysphagic horses usually are hungry and will attempt to eat. Problems with prehension generally suggest a primary neurologic problem. Watching the horse try to graze and eat hay or grain may be necessary. Ingestion of yellow star thistle or Russian knapweed results in basal ganglia lesions (nigropallidal encephalomalacia). Horses with these lesions are unable to prehend food (with lack of coordination of the lips and tongue), but they can swallow.[14] Their ability to drink water should be evaluated carefully, because some horses continue to drink despite having difficulty in swallowing. Horses that expel food while chewing may have problems with mastication. Coughing and nasal discharge indicate aspiration of food into the trachea. Problems with swallowing or regurgitation may cause aspiration. Esophageal obstruction results in regurgitation of food through the nares. Regurgitation often is observed during feeding but may occur shortly after or even hours after feeding. Ptyalism, without dysphagia, may result from ingestion of legume plants (especially second-cutting red clover) contaminated with *Rhizoctonia leguminicola*. This fungus produces a mycotoxin called slaframine, which has parasympathomimetic properties.[19] The excess salivation disappears once the animal stops feeding on the plant. 133

134

3.6.2.2 MORPHOLOGIC ABNORMALITIES

Morphologic abnormalities that cause dysphagia are easier to diagnose than are functional disorders. Morphologic problems of the oral cavity generally result in problems of prehension or mastication. An oral

examination (as outlined earlier) is particularly useful. The passing of a nasogastric tube, endoscopic examination, and radiographs (if necessary) are other diagnostic tests that may help to identify the anatomic localization and cause of dysphagia. Complete obstruction of the esophagus can be excluded if a nasogastric tube is passed successfully into the stomach. Feed impactions of the esophagus are common in horses. Esophageal impactions of feed may occur because of poor mastication or esophageal strictures or diverticulum.[5–7] The most common sites for obstructions occur in the cranial esophagus, at the thoracic inlet, and at the base of the heart.[7] Other esophageal abnormalities include rupture, fistula, cyst, megaesophagus, and neoplasms.[5,20] An endoscopic examination allows visualization of the nasal passageways, nasopharynx, guttural pouches, pharynx, larynx, and esophagus. Inflammation of the pharynx, larynx, or esophagus is assessed best by endoscopic examination. Partial obstructions of the pharynx often result in dyspnea, especially during exercise, and sometimes can cause dysphagia. Retropharyngeal masses, guttural pouch tympany, and rarely neoplasms may result in pharyngeal obstruction and collapse.[2,9,10] Depending on the length of the endoscope available, the clinician can evaluate all or part of the esophagus for inflammation or obstruction.

Radiographs can provide additional information in horses with morphologic causes of dysphagia; however, they are not required in all situations. Radiographs of the skull can help demonstrate the presence of periodontal disease, fractures of the mandible or maxilla, lesions of the temporomandibular joint, or radioopaque foreign bodies.[3] Radiographs of the larynx or pharynx are indicated in cases of pharyngeal obstruction and are especially useful to evaluate retropharyngeal masses, neoplasms, or trauma.[8–10] Radiographs of esophageal perforations reveal subcutaneous air, which shows up as extraluminal radiolucencies.[6] Contrast studies of the esophagus, with the use of barium sulfate, may help differentiate cases of esophageal strictures, dilation, or diverticulum.[5] Radiographs of the thorax are indicated in horses with nasal discharge and abnormal thoracic auscultation because of the concerns of aspiration pneumonia.

3.6.2.3

FUNCTIONAL ABNORMALITIES

Functional disorders that cause dysphagia are more difficult to diagnose and should be pursued after morphologic causes are not identified. The clinician also should consider a functional abnormality if the initial physical examination provides strong evidence of a neurologic, neuromuscular, or muscular problem. The initial step to evaluate functional causes of dysphagia is to perform a neurologic examination. The neurologic examination helps establish a neuroanatomic localization by (1) assessing brain, brainstem, and spinal cord functions; (2) determining if the problem is focal, multifocal, or diffuse; and (3) determining if the problem is a peripheral or central problem.

Cerebral disease usually manifests as seizures, head pressing, wandering, depression, and changes in mentation. Brainstem function can be assessed by cranial nerve examination. Evaluation of an abnormal response of the cranial nerves should establish the location of the problem within the brainstem. For example, the optic nerve can be assessed by the menace response (requiring the facial nerve) and by the pupillary light reflex (requiring the oculomotor nerve). Abnormalities of the oculomotor, trochlear, and abducens nerves manifest as strabismus or lack of a pupillary light reflex. Facial nerve paralysis (ear, eyelid, and muzzle droop) and vestibular disease (circling, nystagmus, and head tilt) often occur together because of the close proximity of these nerves as they exit the brainstem.[21] Endoscopic examination is a valuable tool to determine if pharyngeal or laryngeal paralysis is present. These problems may be caused by peripheral or central diseases. The dorsolateral wall of the medial compartment of the guttural pouch contains a plexus of nerves, including the glossopharyngeal nerve; branches of the vagus, spinal accessory, and hypoglossal nerves; and the cranial

cervical ganglion. Mycotic plaques, empyema, and trauma (hematoma) of the guttural pouch can result in pharyngeal paralysis, dorsal displacement of the soft palate, laryngeal hemiplegia, and occasionally Horner's syndrome.[1,2,11,12,21] The clinician should obtain skull radiographs in many horses with dysphagia, and they are especially helpful when traumatic injuries are suspected. Rupture of the longus capitis muscle results in ventral deviation of the dorsal pharynx and narrowing of the nasopharynx. Bony fragments may be evident ventral to the basisphenoid bones in these horses.[12] Otitis media and pathologic fracture of the petrous temporal bone frequently result in vestibular disease and facial nerve paralysis and occasionally in glossopharyngeal and vagus nerve involvement. An endoscopic examination of the guttural pouches is helpful with this problem, because the distal stylohyoid bone is thickened and irregular. Ventrodorsal, lateral, and rostrolateral oblique radiographs also may reveal osseous changes of the stylohyoid bone, tympanic bulla, or petrous temporal bone.[21]

The clinical examination should include an evaluation of gait. Signs of ataxia, generalized weakness, and hypermetria along with cranial nerve signs may be observable with brainstem involvement. The clinician 134
should evaluate the horse at the walk, trot, down an incline, over a step, and backing and turning in tight 135
circles. The clinician may wish to place the feet of the horse in abnormal positions and determine if the horse can reposition the leg correctly in a reasonable time. Generalized weakness (without ataxia) may manifest with a decrease in tail, eyelid, and tongue tone and muscle fasciculations. Weakness generally suggests a neuromuscular (botulism, organophosphate poisoning) or muscular problem.[16–18] Equine lower motor neuron disease results in generalized weakness and weight loss; however, horses are not dysphagic and do not exhibit cranial nerve abnormalities.[22] Ataxia or hypermetria along with dysphagia suggests a diffuse or multifocal disease that affects the spinal cord and brainstem. Examples of such diseases include equine protozoal myelitis, rabies, equine herpes myeloencephalopathy, polyneuritis equi, and a migrating parasite.[12,23,24] Further diagnostic tests are indicated in these cases, such as an evaluation of spinal fluid for cytologic abnormalities and chemistry and Western blot analysis for antibodies to *Sarcocystis neurona*.[25] Grass sickness, a disease found in Great Britain and in other northern European countries, results in ileus and colic. Grass sickness can result in dysphagia, with problems in swallowing or esophageal transport.[26] Grass sickness is regarded as a fatal disease, resulting in ileus of the gastrointestinal tract, dysphagia, and weight loss, which most likely is caused by an unidentified neurotoxin. Grass sickness can be defined as a dysautonomia characterized by pathologic lesions in autonomic ganglia, enteric plexi, and specific nuclei in the central nervous system.[27] Additional information about the specific causes of dysphagia are covered elsewhere in this text.

3.7 3.7—Respiratory Distress

Bonnie R. Rush

Respiratory distress is defined as labored breathing and is characterized by an inappropriate degree of effort to breathe based on rate, rhythm, and subjective evaluation of respiratory effort.[1] Dyspnea is the sensation of arduous, uncomfortable, or difficult breathing that occurs when the demand for ventilation exceeds the patient's ability to respond.[2] Dyspnea describes a symptom rather than a clinical sign, and although the term often is used, dyspnea is not technically applicable in veterinary medicine. The clinical signs of respiratory distress vary with the severity and origin of impaired gas exchange. Clinical signs commonly observed in horses with respiratory distress include flared nostrils, exercise intolerance, inactivity, exaggerated abdominal effort, abnormal respiratory noise (stridor), anxious expression, extended head and neck, cyanosis, and synchronous pumping of the anus with the respiratory cycle.[1] Horses with chronic respiratory distress may develop a heave line resulting from hypertrophy of the cutaneous trunci and abdominal muscles, which assist during forced expiration.[3] Respiratory distress usually results from inefficient exchange of oxygen and carbon dioxide caused by primary pulmonary disease, airway obstruction, or impairment of the muscles and supporting structures necessary for ventilation. In some cases, ventilation increases in the absence of impaired gas exchange in response to pain, metabolic acidosis, or high environmental temperature. Familiarity with the mechanics of breathing and control of ventilation in healthy and diseased lungs facilitates the diagnosis and treatment of respiratory distress.[3,4]

3.7.1 Control of Ventilation

The partial pressure of oxygen (Pao_2) and carbon dioxide ($Paco_2$) in arterial blood are maintained within a narrow range through rigid control of gas exchange.[2] The center controller of respiration in the medulla alters the rate and depth of respiration via efferent signals to the muscles of respiration in response to afferent signals from chemoreceptors in the peripheral vasculature and central nervous system and mechanoreceptors in the upper and lower respiratory tract, diaphragm, and thoracic wall. The central controller therefore adjusts alveolar ventilation to the metabolic rate of the individual.[4]

3.7.1.1 SENSORS

The chemoreceptors identify changes in metabolism and oxygen requirements and provide feedback to the central controller, thus allowing for modification of ventilation. Central chemoreceptors respond predominantly to hypercapnia, whereas peripheral chemoreceptors respond to hypoxia and hypercapnia. Central chemoreceptors, located in the ventral medulla, monitor alterations in the pH of intracerebral interstitial fluid and cerebrospinal fluid. The blood-brain barrier is impermeable to bicarbonate and hydrogen ions but is freely permeable to carbon dioxide. Therefore acidification of the intracerebral interstitial fluid and stimulation of the central chemoreceptors occur predominantly in response to hypercapnia. The severity of acidosis in the intracerebral interstitial fluid caused by hypercapnia is amplified by two features of the central nervous system: (1) hypercapnia produces cerebral vasodilation, increasing the delivery of CO_2 to the central

nervous system, and (2) cerebrospinal fluid has poor buffering capacity because of low total protein concentrations.[2]

Peripheral chemoreceptors are located in the arterial circulation and respond to acidemia, hypercapnia, and hypoxemia. The carotid bodies are situated at the bifurcation of the common carotid artery, and the aortic bodies are located near the aortic arch. These receptors relay information to the central controller regarding arterial gas tensions via the glossopharyngeal and vagus nerves. Their responsiveness to alterations in $Paco_2$ is less consequential than the central chemoreceptors; however, the peripheral chemoreceptors are solely responsible for the hypoxic ventilatory drive. The peripheral chemoreceptors demonstrate a nonlinear response to low arterial oxygen tension. They are insensitive to alterations in Pao_2 above 100 mm Hg, exhibit moderate response to arterial O_2 tensions between 50 and 100 mm Hg, and demonstrate a dramatic increase in responsiveness when the partial pressure of oxygen falls below 50 mm Hg in the arterial circulation.[2] The respiratory pattern elicited by hypoxia differs from that stimulated by hypercapnia.[5,6] Hypoxia evokes an increase in respiratory frequency, whereas hypercapnia triggers an elevation in tidal volume. In addition, hypoxia stimulates recruitment of the inspiratory muscles, whereas hypercapnia potentiates the activity of inspiratory and expiratory muscles.

The sensitivity of peripheral chemoreceptors should be considered in the treatment of patients with complex acid-base and blood-gas abnormalities. A patient suffering from impaired gas exchange caused by pulmonary disease and metabolic acidosis resulting from shock manifests respiratory distress in response to hypoxemia, hypercapnia, and acidosis. Oxygen supplementation likely will improve the patient's arterial oxygen tension. Such treatment, however, may abolish the hypoxic ventilatory drive and consequently slow the ventilatory rate. This decreased ventilation could exacerbate respiratory acidosis and may result in decompensation of the patient.[4] To avoid life-threatening acidemia, treatment of metabolic acidosis in addition to oxygen supplementation is indicated.

136
137

Receptors located in the upper and lower respiratory tract respond to mechanical and chemical stimuli and relay afferent information to the central controller of respiration via the vagus nerve.[1,2] Vagal blockade abolishes tachypnea in horses with pulmonary disease; therefore these receptors are likely to play an important role in development of respiratory distress associated with primary pulmonary disease.[7–9] Pulmonary stretch receptors, also called slow-adapting stretch receptors, are located within smooth muscle fibers in the walls of the trachea and bronchi.[1,2,4] These receptors are stimulated by pulmonary inflation and inhibit further inflation of the lung (Hering-Breuer reflex). Conversely, at end expiration these receptors stimulate inspiratory activity. These receptors are considered to be partially responsible for controlling the depth and rate of respiration.

Irritant receptors (rapid-adjusting stretch receptors) are believed to be located between epithelial cells of the conducting airways.[2] They are not likely to function in regulation of breathing in a normal resting horse.[4] Stimulation of these receptors by noxious stimuli triggers bronchoconstriction, cough, tachypnea, mucus production, and release of inflammatory mediators.[1,2] Irritant receptors can be triggered by exogenous stimuli (smoke, irritant gases, dust) or by endogenously produced inflammatory mediators including histamine and prostaglandins. Production of histamine, prostaglandins, and other inflammatory mediators increases in horses with chronic obstructive pulmonary disease (COPD).[10–12] Stimulation of irritant receptors by these inflammatory mediators may be responsible in part for bronchoconstriction, mucus production, and tachypnea observed in horses with allergic airway disease. In addition to their role as chemoreceptors, irritant receptors also function as mechanoreceptors.[1] An abrupt change in end-expiratory lung volume, such as occurs with pneumothorax or pleural effusion, produces a tachypneic breathing pattern attributed to stimulation of irritant

receptors. Juxtacapillary receptors are believed to be located within the wall of the alveolus. Stimulation by increased interstitial fluid volume triggers the sensation of difficult breathing.[2] Nonmyelinated C fibers are located in the pulmonary parenchyma, conducting airways, and blood vessels. These receptors respond to pulmonary edema, congestion, and inflammatory mediators, and stimulation activates a tachypneic breathing pattern. In addition, C fiber receptors may stimulate the release of pulmonary neuropeptides, which produce bronchoconstriction, vasodilation, protein extravasation, and cytokine production.[1] Increased negative pressure (upper airway obstruction) within the airway stimulates mechanoreceptors of the larynx and produces prolongation of inspiratory time and activation of upper airway dilator muscles.[13]

3.7.1.2 CENTRAL CONTROL OF RESPIRATION

The central controller consists of a group of motor neurons in the pons and medulla that receive input from the peripheral and central receptors and initiate phasic activity of diaphragmatic, intercostal, and abdominal respiratory muscles.[2] The medullary respiratory center, which is located in the reticular formation, controls the rhythmic pattern of respiration. The dorsal respiratory group coordinates inspiratory activity by assimilating afferent information from the glossopharyngeal and vagus nerves and transmits efferent signals to the muscles of inspiration and neurons in the ventral respiratory group. The ventral respiratory group consists of inspiratory and expiratory motor neurons. This nucleus is relatively inactive at rest and has a more dominant role during exercise. The apneustic center, located in the pons, provides stimulatory input to inspiratory motor neurons. Damage to the apneustic center, from trauma or neonatal maladjustment syndrome, results in prolonged inspiratory gasps interrupted by transient expiratory efforts.[4] The pneumotaxic center, also located in the pons, inhibits the inspiratory centers and regulates the volume and rate of respiration. The pneumotaxic center is not required to maintain a normal respiratory rhythm; instead, this center functions to fine tune the respiratory rhythm,[2] receiving afferent input from the vagus nerve regarding Pao_2, $Paco_2$, and pulmonary inflation.

3.7.1.3 EFFECTORS OF RESPIRATION

The muscles required for ventilation include the diaphragm, the external and internal intercostal muscles, and the abdominal muscles. The single most important muscle required for the inspiratory phase of the respiratory cycle is the diaphragm. Contraction of the diaphragm forces the abdominal contents back, increasing the length of the thoracic cavity, and pulls the ribs abaxially, increasing the width of the abdominal cavity. In addition, the external intercostal muscles participate in inspiration by pulling the ribs abaxially to increase the width of the thoracic cavity. The net effect is an increase in the size of the thoracic cavity, producing subatmospheric intrathoracic pressure, to drive inspiration and pulmonary inflation. Expiration at rest is a passive process in most species and relies on elastic recoil of the lung to create positive intrathoracic pressure.[14] In horses, the first portion of expiration relies on elastic recoil of the lung to the point of relaxation volume, whereby the tendency for pulmonary collapse equals the tendency for expansion by the thoracic wall. 137
However, horses further decrease lung volume by active compression of the chest wall, through contraction of 138
the internal intercostal muscles and muscles of the abdominal wall.[15] Conversely, the first part of inhalation is passive until the relaxation volume is reached, at which point the diaphragm and external intercostal muscles complete the inspiratory phase. Mechanical (abdominal distention, trauma to the thoracic wall) and neuromuscular (botulism, phrenic nerve damage, nutritional muscular dystrophy) dysfunction of the diaphragm and intercostal muscles prevent expansion of the thoracic wall and produce hypoventilation, hypoxemia, and respiratory distress.[4] Horses with torsion of the large colon develop significant abdominal

distention and respiratory distress. Respiratory failure caused by impaired diaphragmatic function plays an important role in the pathophysiology and mortality associated with this intestinal accident.

The diameter of the conducting airways is an important determinant of the degree of pulmonary resistance and work of breathing and is controlled by the autonomic nervous system. Vagal-mediated parasympathetic stimulation causes airway narrowing and is one mechanism of bronchoconstriction associated with allergic airway disease. Administration of atropine results in rapid relief of bronchoconstriction in some horses with COPD, demonstrating the important role of parasympathetic bronchoconstriction in the pathogenesis of this disease.[16,17] β_2-Receptor stimulation produces smooth muscle relaxation and bronchodilation. β_2-Adrenergic receptors are abundant throughout the lung; however, sympathetic innervation is sparse and β-receptors within the lung must rely on circulating catecholamines for stimulation.[4] Airways must be constricted for β_2-receptor stimulation or atropine blockade to produce increased airway caliber.[18,19] β-Adrenergic receptors are less abundant than β_2-receptors and play no important role in the regulation of airway diameter. However, α-receptors appear to be upregulated in horses with COPD and contribute to bronchoconstriction associated with this disease.[20]

Nonadrenergic-noncholinergic (NANC) innervation also contributes to large airway diameter. Smooth muscles of the trachea and bronchi relax in response to activation of the inhibitory NANC system. In COPD-affected horses with clinical signs of airway obstruction, inhibitory NANC function is absent.[21] Failure of the inhibitory NANC system may result from the inflammatory response during acute COPD or may be an inherent autonomic dysfunction of the conducting airways of COPD-affected horses.

3.7.2 Hypoxemia

Respiratory distress most often originates from inadequate pulmonary gas exchange to meet the metabolic demands of the individual, resulting in hypoxia and hypercapnia. Hypoxia results from one or more of five basic pathophysiologic mechanisms: hypoventilation, ventilation-perfusion mismatch, right to left shunting of blood, diffusion impairment, and reduced inspired oxygen concentration. The degree of hypercapnia and response to oxygen supplementation varies depending on the mechanism of impaired gas exchange. Determination of these two parameters is useful in identifying the pathophysiologic process predominantly responsible for the development of hypoxia.[22]

3.7.2.1 HYPOVENTILATION

The hallmark of hypoventilation is hypercapnia.[22] The elevation in $Paco_2$ is inversely proportional to the reduction in alveolar ventilation; halving alveolar ventilation doubles $Paco_2$.[2] The reduction in arterial oxygen tension is almost directly proportional to the increase in CO_2. For instance, if $Paco_2$ increases from 40 to 80 mm Hg, then the Pao_2 decreases from 100 to 60 mm Hg. Therefore hypoxemia resulting from hypoventilation is rarely life-threatening. In addition, oxygen supplementation easily abolishes hypoxemia caused by pure hypoventilation. Acidosis caused by hypercapnia is the most clinically significant feature of hypoventilation and may threaten the life of the patient.[22] Metabolic alkalosis or central nervous system depression (head trauma, encephalitis, narcotic drugs) can produce hypoventilation; however, horses with these disorders may not demonstrate clinical signs of respiratory distress. The following disorders can cause alveolar hypoventilation, and affected patients usually demonstrate clinical signs of respiratory distress: mechanical (abdominal distention, trauma to the thoracic wall) and neuromuscular (botulism, phrenic nerve damage,

nutritional muscular dystrophy) dysfunction of the diaphragm and intercostal muscles, restrictive pulmonary disease (silicosis, pulmonary fibrosis, pneumothorax, pleural effusion), and upper airway obstruction.[4]

3.7.2.2 VENTILATION-PERFUSION MISMATCH

Ventilation-perfusion (V-Q) mismatch is the most common cause of hypoxemia and is characterized by unequal distribution of alveolar ventilation and blood flow.[4] Pulmonary regions that are overperfused in relation to ventilation (low V-Q ratio) contribute disproportionate amounts of blood with low arterial oxygen content to the systemic circulation.[2,22] Respiratory diseases characterized by low V-Q ratios include COPD, pulmonary atelectasis, and consolidation.[4] If ventilation exceeds perfusion (high V-Q ratio), the ventilated pulmonary units are inefficient for CO_2 elimination and O_2 uptake. Ventilation of poorly or nonperfused units is wasted ventilation, termed *alveolar dead space*.[2,22] Conditions associated with high V-Q ratios include pulmonary thromboembolism and shock (low pulmonary artery pressure). Patients with V-Q mismatch often 138
have a normal arterial Pco_2. The ventilatory drive to maintain normal $Paco_2$ is powerful. Because the CO_2 139
dissociation curve is basically a straight line (direct relationship), increased ventilation efficiently decreases $Paco_2$ at high and low V-Q ratios. Because the nearly flat shape of the O_2 dissociation curve, increasing ventilation is inefficient for proportionally increasing the arterial Po_2. Only pulmonary units with moderate to low V-Q ratios benefit from increased ventilation. Therefore the increased ventilatory effort to maintain normal $Paco_2$ is wasted and unnecessarily increases the work of breathing. Oxygen supplementation increases $Paco_2$ in patients with a V-Q mismatch. However, elevation in arterial O_2 is delayed compared with hypoventilation and in some cases may be incomplete.[22] Compensatory mechanisms are present to minimize unequal distribution of ventilation and perfusion in diseased lungs to prevent the development of hypoxemia until pulmonary pathologic condition is severe.[23] Reflex pulmonary arterial constriction (hypoxic vasoconstriction) prevents perfusion of unventilated alveolar units and attempts to redirect blood flow to alveoli that are ventilated adequately. Airway hypocapnia causes bronchoconstriction of airways that conduct to unperfused alveolar units, redirecting air flow to better perfused alveoli.

3.7.2.3 SHUNT

Shunt is defined as blood that is not exposed to ventilated areas of the lung and is added to the arteries of the systemic circulation.[22] Shunting can occur as an extreme form of V-Q mismatch or with direct addition of unoxygenated blood to the arterial system. *Physiologic shunting* is defined as perfusion of nonventilated or collapsed regions of the lung and occurs with pulmonary consolidation, atelectasis, and edema. Congenital heart disease, such as tetralogy of Fallot and some cardiac septal defects, is an example of a direct right-to-left shunt wherein unoxygenated blood from the right side of the heart is added to oxygenated blood from the left side of the heart. In these conditions, hypoxemia cannot be abolished by increasing the oxygen content of inspired air. The shunted blood is never exposed to the higher concentration of inspired oxygen in the alveolus, and the addition of a small amount of shunted blood with its low O_2 content greatly reduces the Po_2 of arterial blood. Compared with breathing room air, the decrement in Po_2 is much greater at Po_2 levels associated with the inhalation of O_2-enriched air because the O_2 dissociation curve is so flat at high Po_2 levels. Only hypoxemia caused by right-to-left shunting behaves in this manner when the patient is permitted to inspire high percentages of oxygen (70% to 100%). Shunts do not usually cause hypercapnia.[23] Chemoreceptors detect excess arterial CO_2, and ventilation increases to reduce the content of CO_2 in

unshunted blood until arterial Pco_2 reaches the normal range. In some cases of shunt, the arterial Pco_2 is below normal because of hyperventilation stimulated by the hypoxemic ventilatory drive.

3.7.2.4 DIFFUSION IMPAIRMENT

Gas exchange between the alveolus and the capillary occurs by passive diffusion, which is driven by the property of molecules to move randomly from an area of high concentration to one of low concentration.[23] Factors that determine the rate of gas exchange include the concentration gradient between the alveolus and capillary blood, solubility of the gas, surface area available for diffusion, and the width of the air-blood barrier. Diseases characterized by pure diffusion impairment are rare in veterinary medicine.[4] Diffusion impairment can occur with pulmonary fibrosis, interstitial pneumonia, silicosis, or edema caused by increased width of the barrier or decreased surface area available for gas exchange. The clinician should recognize that the major component of hypoxemia for these conditions is a V-Q mismatch; however, diffusion impairment can contribute to the severity of hypoxemia. Supplemental oxygen therapy is effective in treating hypoxemia caused by diffusion impairment because it creates a more favorable concentration gradient and increases the driving pressure of oxygen to move from the alveolus into the blood. Transport of CO_2 is less affected by diseases of diffusion impairment because of its greater solubility compared with O_2.[23]

3.7.2.5 REDUCTION OF INSPIRED OXYGEN

Hypoxemia resulting from decreased inspired oxygen content is uncommon and occurs only under special circumstances. High altitude and iatrogenic ventilation with a low oxygen concentration are the most common circumstances in which hypoxemia is attributed to reduction of inspired oxygen content.[22]

Most pulmonary diseases in horses incorporate more than one of these pathophysiologic mechanisms for the development of hypoxemia. Horses with pleuropneumonia, for example, may develop hypoxemia caused by hypoventilation (extrapulmonary restriction by pleural effusion), V-Q mismatch (accumulation of exudate and edema within alveoli and conducting airways), and diffusion impairment (exudate and edema within the interstitial spaces).

3.7.3 Obstructive Disease

The location (intrathoracic or extrathoracic) and nature (fixed or dynamic) of airway obstruction determines whether impedance to air flow occurs during inspiration, expiration, or both.[3] The phase of the respiration cycle affected by air flow obstruction are prolonged and may be associated with a respiratory noise (stridor or wheeze).[24,25] 139

140

The horse is an obligate nasal breather and can only breathe efficiently through the nares.[4] Therefore upper airway obstruction within the nasal passages cannot be bypassed by mouth breathing. In addition, approximately 80% of the total airway resistance to air flow is located in the upper airway.[25] A 50% decrease in the radius of an airway increases its resistance by sixteenfold (Poiseuille's law).[14] Therefore small changes in the upper airway diameter dramatically affect the overall resistance to air flow and work of breathing for the horse. Extrathoracic airway pressures are subatmospheric during inspiration; therefore poorly supported structures in the upper airway narrow or collapse during inspiration (dynamic collapse). The most common cause of non–fixed upper airway obstruction in horses is laryngeal hemiplegia, which produces inspiratory stridor during exercise.

Intraluminal masses and arytenoid chondritis cause fixed upper airway obstruction and produce inspiratory and expiratory respiratory distress.[3]

Twenty percent of the total airway resistance is attributable to the small airways.[25] Although the radius of individual bronchioles is small, many of them exist and the sum or collective radius is large, with the result that their overall contribution to pulmonary resistance is low.[23] Because the resistance of the bronchioles is low, advanced disease must be present for routine measurements of airway resistance to detect an abnormality, and obstruction of these airways must be extensive before a horse would suffer from respiratory distress. During pulmonary inflation, intrathoracic pressures are subatmospheric. Small airways are pulled open by negative intrathoracic pressure and stretched parenchymal attachments at high lung volumes. Thus resistance to air flow in small airways is low during the inspiratory phase of respiration.[24] During exhalation, intrathoracic pressure is positive and the diameter of small airways is decreased, and bronchioles may even close at low lung volumes. Therefore resistance to air flow in small airways is greatest during the expiratory phase. In horses with COPD, the airway diameter is reduced by inflammatory exudate, edema, and bronchoconstriction.[16,17] As lung volume decreases during expiration, the narrowed bronchioles are compressed shut (dynamic airway collapse) and trap air distal to the site of closure.[4] This is an example of severe flow limitation, which may lead ultimately to the development of emphysema. Flow limitation forces horses with COPD to breathe at higher lung volumes and maintain a higher functional residual capacity to reduce or avoid dynamic airway collapse. Affected horses attempt to reduce the end-expiratory lung volume by recruiting abdominal muscles to increase the intrathoracic pressures during expiration. However, the greater the end-expiratory pressure, the greater is the likelihood of small airway compression and collapse. Hypertrophy of the cutaneous trunci and expiratory abdominal muscles, especially the external abdominal oblique, produces the characteristic heave line associated with COPD.[4] Because dynamic airway narrowing and collapse occurs during exhalation, wheezes are loudest at end expiration in horses with COPD.[16,17]

3.7.4 Restrictive Disease

Restrictive disease is less common than is obstructive pulmonary disease in horses.[4] By definition, restrictive disease inhibits pulmonary expansion and leads to inspiratory respiratory distress.[26] The vital capacity and compliance (pulmonary or chest wall) decrease, expiratory flow rates and elastic recoil increase, and airway resistance is normal. The characteristic respiratory pattern in horses with restrictive pulmonary disease is rapid, shallow respiration at low lung volumes.[4] This strategy takes advantage of high pulmonary compliance at low lung volumes and decreases the work of breathing. This respiratory pattern has the disadvantage of increased ventilation of anatomic dead space.[26] Restrictive diseases may be classified as intrapulmonary (pulmonary fibrosis, silicosis,[27] and interstitial pneumonia[28,29]) and extrapulmonary (pleural effusion, pneumothorax, mediastinal mass, botulism, and nutritional muscular dystrophy).[4] Hypoxemia observed in horses with intrapulmonary restrictive disease is attributed to V-Q mismatch and diffusion impairment. Stimulation of juxtacapillary receptors may contribute to respiratory distress observed in these patients.[26] The pathophysiologic mechanism for hypoxemia in horses with extrapulmonary restriction is hypoventilation.[4] In cases of pleural effusion and pneumothorax, respiratory distress is likely to be exacerbated by thoracic pain.

3.7.5 Nonpulmonary Respiratory Distress

Respiratory distress does not always originate from dysfunction of the pulmonary system and its supporting structures. Nonpulmonary respiratory distress can occur because of inadequate oxygen-carrying capacity of the blood, compensation for metabolic acidosis, pain, and hyperthermia.

Impaired oxygen-carrying capacity of the blood may occur because of anemia (blood loss, hemolytic, or aplastic) or dysfunction of red blood cells (methemoglobinemia, carbon monoxide toxicity). In these cases, the arterial Po_2 tension is normal; however, the oxygen content of the blood is reduced greatly.[2] Tachypnea and respiratory distress occur in response to impaired oxygen delivery and tissue hypoxia.[3]

The respiratory system can compensate for metabolic acidosis by increasing ventilation to lower $Paco_2$ and 140
attenuate acidemia.[2] The ventilatory drive increases in response to stimulation by peripheral chemoreceptors by 141
circulating hydrogen ions. Hypocarbic compensation for mild to moderate metabolic acidosis is effective in returning blood pH to normal until renal compensatory mechanisms can be established.[2]

Pain and anxiety are physiologic causes of tachypnea and hyperpnea. Horses with musculoskeletal pain are unlikely to demonstrate significant respiratory distress; however, rhabdomyolysis and laminitis are painful musculoskeletal conditions that may produce tachypnea.[3] Marked respiratory distress is observed frequently in horses with abdominal pain; however, the respiratory distress is not caused solely by pain and is exacerbated by abdominal distention, shock, acidosis, and endotoxemia.

Hyperthermia caused by fever, high environmental temperature, exercise, and heat stress can produce respiratory distress in horses. Tachypnea and elevation in body temperature are the most prominent clinical signs in horses with anhydrosis.[30] Hyperpnea is an effective mechanism for heat dissipation in human beings, dogs, and ruminants.[3] Unfortunately, increased ventilation is an inefficient mechanism for heat dissipation in horses and appears to be wasted effort.[3,4]

3.7.6 Clinical Evaluation of Respiratory Distress

A thorough physical examination is essential to determine the origin of respiratory distress, identify concurrent disease, and direct further diagnostic testing. Prolonged inspiration is consistent with restrictive or extrathoracic, nonfixed, obstructive disease, whereas horses with intrathoracic airway obstruction exhibit expiratory difficulty.[3,24] Respiratory distress associated with inspiration and expiration may indicate an extrathoracic fixed obstruction. Stridor is an abnormal respiratory noise that usually is generated by obstruction of the upper airway and is audible most often during inspiration.[3] Horses with nonpulmonary respiratory distress demonstrate increased rate and depth of respiration, without producing abnormal respiratory noise.

Thoracic auscultation identifies abnormal respiratory sounds (crackles and wheezes) or regions of decreased breath sounds caused by pleural effusion, pneumothorax, or pulmonary consolidation. Percussion of the thoracic wall generates a resonant and hollow sound when performed over regions of normal lung. Pleural effusion and pulmonary consolidation sound dull and flat during thoracic percussion, whereas pneumothorax produces a hyperresonant sound.[31]

Normal air flow occurs in laminar flow; therefore normal horses at rest do not generate easily audible sounds.[4] Respiratory sounds are generated from vibration in tissue and sudden changes in pressure of gas moving within the airway lumen. Airway narrowing and exudate generate audible sounds by creating disturbances in laminar flow, turbulence, and sudden changes in pressure of moving gas.[14] Crackles are intermittent or explosive sounds, generated by bubbling of air through secretions or by equilibration of airway pressures after sudden opening of collapsed small airways. The generation of crackles requires an air-fluid interface, and these abnormal lung sounds occur in horses with pneumonia, interstitial fibrosis, COPD, pulmonary edema, and atelectasis.[4] Wheezes are continuous, musical sounds that originate from oscillation of small airway walls before complete closing (expiratory wheeze) or opening (inspiratory wheeze).[14] Expiratory wheezes are the hallmark of obstructive pulmonary disease.[24]

Arterial blood gas determination provides a quantitative evaluation of pulmonary function, alveolar ventilation, and acid-base status and may identify the origin of respiratory distress (hypercapnia, hypoxemia, or acidemia).[22] The clinician may determine the pathophysiologic mechanism of hypoxemia by examining the $Paco_2$ level and by investigating the response of Pao_2 to supplemental oxygen therapy. In addition, serial blood gas monitoring can determine response to bronchodilator, parasympathomimetic, or antiinflammatory therapy.

Additional diagnostic tests that may be indicated in horses with respiratory distress include thoracic radiography, thoracic ultrasonography, endoscopic examination of the upper airway, and atropine challenge. The findings during thoracic auscultation and percussion are valuable in determining indication for ultrasonography versus radiography. Pulmonary consolidation, abscessation, fibrosis, interstitial pneumonia, peribronchial infiltration, and mediastinal mass are differentiated and diagnosed readily via thoracic radiography. Thoracic ultrasonography is superior to radiography in detecting and characterizing pleural fluid and peripheral pulmonary abscessation and consolidation in horses. Air reflects the ultrasound beam; therefore ultrasonography does not image deep pulmonary lesions if the overlying lung is aerated.[32] An endoscopic examination of the upper airway is indicated in horses with inspiratory stridor and suspected upper airway obstruction.[33] Horses with extreme respiratory distress may resent endoscopic examination, and forced examination may precipitate a respiratory crisis. Atropine administration in horses with COPD may provide rapid relief of respiratory distress, if the major component of airway obstruction is reversible bronchoconstriction. Horses that respond to an atropine challenge likely will respond favorably to bronchodilator therapy. Incomplete response to atropine in horses with COPD indicates that exudate or fibrosis is contributing to airway obstruction, and limited response to bronchodilator therapy is anticipated.[16,17] 141

3.8

3.8—Cough

Catherine W. Kohn

Cough, a sudden explosive expulsion of air through the glottis, is a common sign of respiratory disease and a reflex pulmonary defense mechanism. Coughing facilitates the removal of noxious substances and excessive secretions from the airways by creating maximum expiratory airflow. A high-velocity airflow generates the shear forces required to separate mucus from the airway walls, enabling expulsion of exudate and debris from the airway.[1] An understanding of the cough reflex provides insight into the pathophysiology of diseases characterized by cough.

The cough reflex has been studied infrequently in horses. Descriptions of the cough cycle and the neural basis of cough presented in this section are based on data from other species. The author infers that similar events occur in 142
horses. Because differences exist among species regarding the cough reflex,[2] studies on horses will be required to 143
define the physiologic events of the cough reflex in this species.

3.8.1

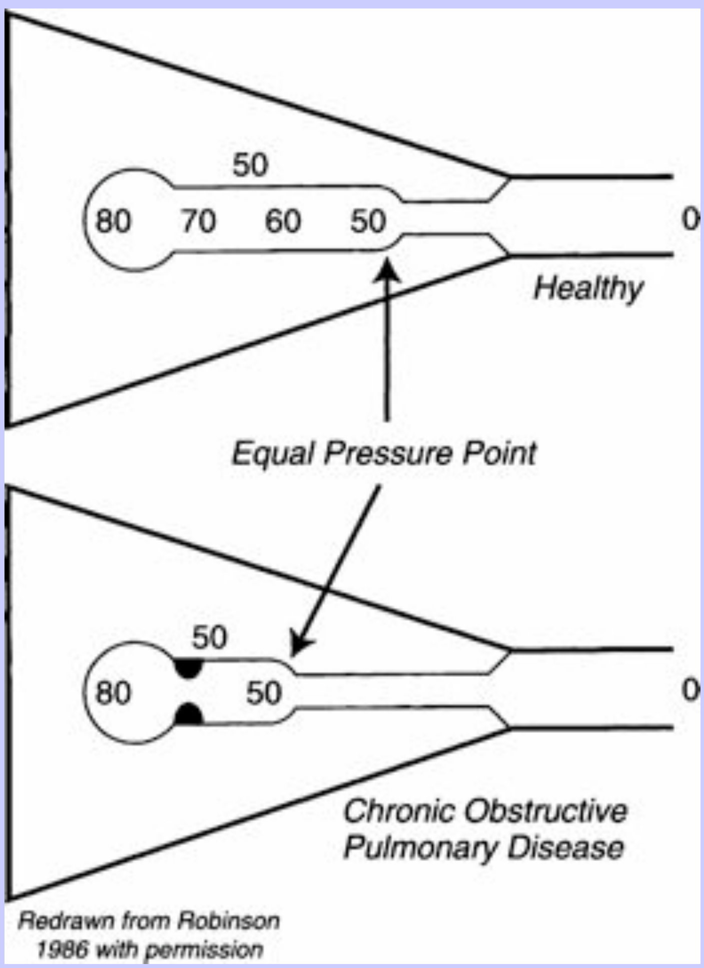
Cough Cycle

The cough cycle has four phases: inspiration, compression, expression, and relaxation.[1] Deep *inspiration,* which immediately precedes cough, increases lung volume. As lung volume increases, the ability to generate maximum expiratory airflow increases because of the greater force of contraction achieved by the muscles of respiration when their precontraction length increases and because of the greater elastic recoil pressure of the lung at high lung value.[3] Thus precough expansion of lung volume maximizes the velocity of expiratory airflow. Achievement of maximum expiratory airflow rates requires a relatively gentle expiratory effort, and airflow maxima are therefore independent of effort.[2]

After deep inspiration, the glottis closes. While the glottis remains closed, *compression* of the chest cavity occurs by contraction of the thoracic and abdominal musculature during an active expiratory effort. Compression of the chest results in an increase in pleural pressure from 50 to 100 mm Hg.[2] This increase in pleural pressure is transmitted to pressure in the intrathoracic airways and trachea. Intraalveolar pressures actually exceed intrapleural pressures by an amount equal to the elastic recoil pressure of the lung.[4]

Expression occurs when the glottis opens abruptly, thus producing a gradient in airway pressure (atmospheric at the pharynx and high in the alveoli), and air is expired forcefully. The occurrence of dynamic airway compression in larger airways maximizes the velocity of airflow toward the mouth (Figure 3.8-1). The intraairway pressures vary in the respiratory system according to the instantaneous transpulmonary pressure.[3] At the equal pressure point, the airway pressure equals the pleural pressure. Toward the mouth from the equal pressure point (downstream), the pleural pressure is greater than intrathoracic airway pressure, and the intrathoracic airways therefore are compressed dynamically. Partial collapse of the airways downstream of the equal pressure point maximizes airflow velocities in these airways by decreasing their diameter. At high lung volumes, the equal pressure point likely is in the larger airways and therefore only the intrathoracic trachea may be subject to dynamic compression and maximal airflow velocity.[4] Maximum airflow velocity produces high shearing forces that dislodge mucus and debris from airway walls, thus facilitating expectoration. Cough is therefore most effective as a defense mechanism for clearing the larger airways in healthy animals. Removal of noxious substances from the smaller peripheral airways depends on the presence of mucus in the airways, and irritants that stimulate cough also may stimulate mucus production.[5]

Figure 3.8-1 Dynamic airway compression during cough or maximum expiratory airflow. Lungs are represented at total lung capacity. When chronic obstructive pulmonary disease is present, the equal pressure point moves toward the alveoli. This peripheral migration of the equal pressure point results in dynamic compression in more peripheral airways during cough than would be found in a healthy individual. (Redrawn from Robinson NE: Pathophysiology of coughing. In Proceedings of the thirty-second convention of the American Association of Equine Practitioners, Nashville, 1986, pp 291-297.)



In diseases characterized by increased resistance in small peripheral airways caused by partial obstruction (e.g., chronic obstructive pulmonary disease [COPD]), maximal expiratory flow rates are reduced. When small airways are obstructed partially, the equal pressure point moves toward the periphery of the lung during

coughing because pressures in airways downstream of the partial obstruction are lower than are pressures in those airways in healthy lungs (see Figure 3.8-1). This shift in the equal pressure point subjects more peripheral airways to dynamic compression. Coughing is likely to be less effective as a clearance mechanism when obstructive diseases of the small airways are present. Bronchodilator therapy may increase the effectiveness of cough in such patients by increasing expiratory airflow rates.[4]

The sound of cough is generated by vibration of laryngeal and pharyngeal structures caused by the rapid expulsion of air immediately after opening of the glottis,[3] by narrowing and deformation of airways, and by 143
vibration of surrounding lung tissue. Variations in the sound of cough most likely relate to the quantity and 144
quality of mucus in the airway.[6]

At the end of cough, *relaxation* occurs. Intrapleural pressure falls, and the muscles of expiration relax. Transient bronchodilation occurs.[1]

3.8.2 Neural Basis of the Cough Reflex

The afferent input for the cough reflex is carried predominantly in the vagus nerves, and the cough reflex depends uniquely on vagal afferents in the species studied.[5,7,8] Sensory myelinated nerves in the larynx respond to mechanical and chemical irritation and mediate cough and changes in airway diameter.[7] Debate continues about the identity of receptors that initiate cough in the lower airways; however, all the receptors described is this section likely contribute to the cough response.[8] *Rapidly adapting receptors* are located in the airway mucosa in the region of the carina and are stimulated primarily by mechanical deformation produced, for example, by inhaled particles, mucus, or cellular debris accumulating near the carina. Chemical irritants (e.g., ammonia fumes, ozone, and inflammatory mediators) evoke cough by stimulation of receptors located in the peripheral airways. *Pulmonary C fibers* may mediate a chemically evoked cough, although this issue still is debated. Chemical mediators known to stimulate pulmonary C fibers and cough when inhaled as aerosols by human beings include bronchodilator prostaglandins, bradykinin, and capsaicin.[8] Forced expiration during coughing may be facilitated by the modulating effects of information from these receptors on central respiratory neurons.

Bronchoconstriction is a constant component of cough,[3,6] and stimuli of cough also may cause bronchoconstriction; however, cough and bronchoconstriction are separate airway reflexes. Inhalation of dust and irritant gases causes reflex bronchoconstriction in the species studied. Reflex bronchoconstriction has a slow onset and is long lasting compared with the cough reflex.[9] Bronchoconstriction may increase the efficiency of cough by decreasing airway diameter and therefore increasing airflow velocity. In some cases, bronchodilating drugs may suppress the cough reflex by desensitizing airway receptors that elicit cough.[6]

Sensory nerves mediating bronchoconstriction and cough are distributed unevenly along the airways.[7] Laryngeal receptors and sensory nerves in the extrapulmonary airways may be more sensitive to mechanical stimuli, whereas intrapulmonary receptors may respond preferentially to chemical mediators and irritants.

Little is known about the brainstem neuronal pathways of the cough reflex. In the cat, the cough center is reported to be in the medulla at the level of the obex, alongside the solitary nucleus of the vagus and close to the expiratory neurons of the respiratory center. On the motor side of the cough reflex, the vagal, phrenic, intercostal, and lumbar nerves and motor portions of the trigeminal, facial, hypoglossal, and accessory nerves are

distributed to the striated and smooth muscles of respiration, the vocal fold abductors and adductors, and glands of the respiratory tract.[3]

3.8.3 Stimuli of Cough

Cough may be stimulated by airway smooth muscle contraction (bronchoconstriction), excessive mucus production, presence of inhaled particles in the airways, release of inflammatory mediators (infectious diseases), exposure to cold or hot air, intramural or extramural pressure or tension on the airways (tumor, granuloma, abscess, or decreased pulmonary compliance caused by restrictive disease such as interstitial fibrosis or pleuritis), sloughing of airway epithelial cells, and enhanced epithelial permeability (pulmonary edema).[5] Epithelial sloughing and enhanced epithelial permeability theoretically increase the accessibility of cough receptors to the mechanical or chemical agents that stimulate them. Loss of the integrity of the epithelial lining of the respiratory tract is a common feature in many respiratory diseases associated with cough (infectious diseases); however, a cause-and-effect relationship between alterations in respiratory epithelium and cough has not been established.[5]

Diseases of the respiratory tract may alter the sensitivity of the cough reflex.[5] For example, viral diseases may increase the responsiveness of cough receptors to stimuli.

3.8.4 Deleterious Consequences of Cough

Although cough is an important defense mechanism of the respiratory system that promotes expectoration of inhaled noxious substances and voluminous airway secretions, cough may lose its original defensive function and may contribute to the morbidity and discomfort associated with bronchopulmonary disease.[8] This is especially true when the effort to cough is intense and when multiple coughs occur sequentially. Chronic coughing is exhausting and, especially in foals, may decrease food intake. Paroxysmal or persistent cough may impair respiration. Coughing may have profound effects on the cardiovascular system. During the deep inspiratory phase of cough, the rise in intraabdominal pressure because of contraction of the diaphragm and the fall in intrathoracic pressure combine to aspirate blood from the vena cava to fill the right atrium and ventricle abruptly.[3] Because the pleural pressure decreases, the pulmonary artery pressure also decreases. During the expiratory phase of cough, an initial increase in systemic arterial blood pressure and a simultaneous and commensurate increase in cerebral venous and cerebrospinal fluid pressures occur. However, venous return to the heart soon decreases and within a few heartbeats, filling of the heart and stroke volume decrease.[2,3] Hypotension ensues. Falling arterial blood pressure in the face of high cerebral venous pressures reduces the effective perfusion pressure of the brain. Cerebral hypoperfusion and anoxia may occur. Cough-induced syncope has been reported in human beings[2] and in dogs.[10]

In chronic cough, bronchial muscular hypertrophy may develop. Bronchial mucosal edema or emphysema may accompany chronic cough. During cough inspiration, inflammatory debris may be aspirated into previously uncontaminated areas of the lung. Cough in dogs has been associated with pneumothorax (from rupture of preexisting pulmonary bullae) and lung lobe torsion.[11] Rib and vertebral fractures have been reported in human beings with powerful coughs but have not been reported in horses.[2,3]

3.8.5 Clinical Approach to the Coughing Horse

Cough is a common sign of respiratory disease in horses (Figure 3.8-2). Cough is an indication of mechanical or irritant stimulation of cough receptors for which the potential causes are diverse. Many clinical approaches exist for anatomic localization of the origin of the cough stimulus in respiratory disease and for discovery of the cause. All methods have in common a systematic and thorough evaluation of the history and physical examination of the patient. To aid the clinician in formulating a rational approach to diagnosis, diseases associated with cough may be grouped according to those characterized by fever (current or historical) and those characterized by lack of an elevated body temperature. The clinician should keep in mind that exceptions to generalizations always occur concerning disease processes, and the following discussion therefore serves only as a guide to develop a logical approach to differenting diseases characterized by cough.

3.8.5.1 COUGH WITH FEVER

Horses with cough and fever should have a thorough physical examination (see Chapter 7 for a complete description of a physical examination for horses with respiratory disease). A minimum laboratory database for the coughing horse with fever should include the results of a hemogram and a fibrinogen determination. The clinician carefully should auscultate the thorax of the horse in a quiet room with the horse breathing quietly. If the horse is not dyspneic or hypoxemic, the clinician also should undertake auscultation during forced breathing. A plastic bag loosely held over the nostrils of the horse forces the horse to increase tidal volume and respiratory rate. This maneuver causes many horses with exudate in the airways to cough, and deep breathing may be frankly painful for some horses with pleuropneumonia. Auscultation during forced breathing is not necessary in horses with obviously abnormal lung sounds during quiet breathing and is not advisable in horses with pneumonia (especially aspiration pneumonia) or in horses with foreign material in the trachea. Crackles and wheezes heard repeatedly during the inspiratory and early expiratory phases of breathing suggest that pulmonary parenchymal disease is present. Accentuated normal bronchovesicular sounds sometimes are present in horses with pulmonary consolidation, because of referral of sounds from the aerated lung. Absence of lung sounds in dependent portions of the thorax indicates that pulmonary consolidation, atelectasis, or fluid in the pleural cavity may be present. Thoracic percussion and sonographic evaluation are particularly helpful in documenting the presence of fluid in the pleural cavity. Ultrasonography also may show pleural irregularities and superficial parenchymal abscessation, atelectasis, or consolidation. Thoracic radiographs are especially helpful in demonstrating deeper parenchymal disease. Many equine practitioners do not have access to thoracic radiography but can perform thoracic ultrasonography.

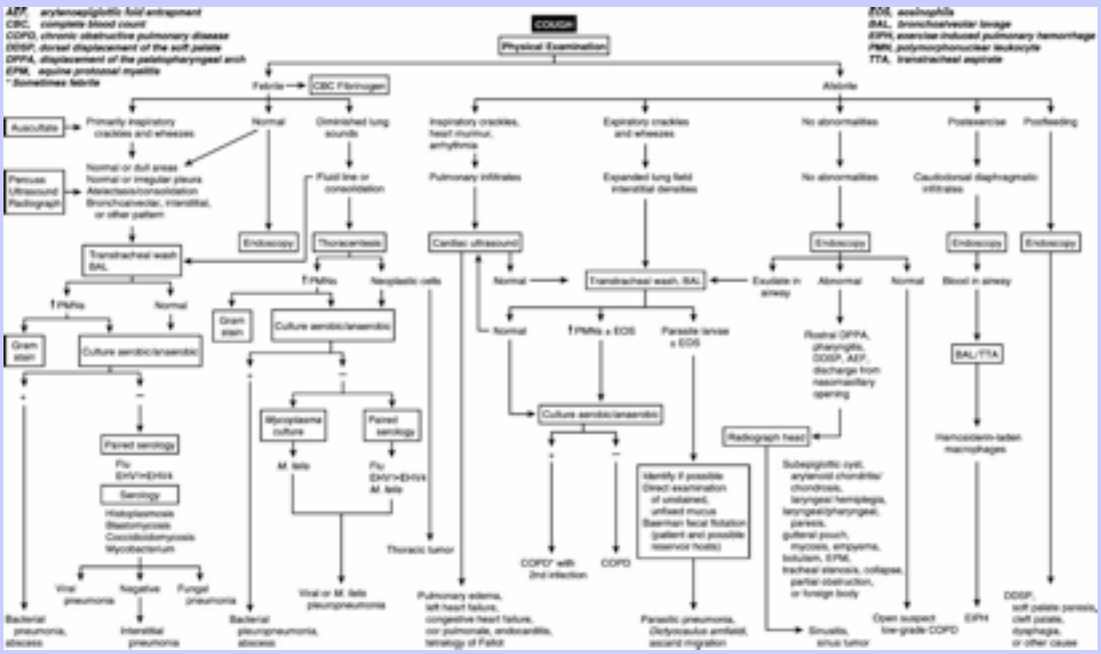
Abnormal lung sounds, percussion irregularities, and sonographic evidence of fluid or consolidation are indications for performing transtracheal aspiration (TTA) and bronchoalveolar lavage (BAL). When both procedures are to be performed on the same patient, the clinician should perform TTA first to obtain a sample for culture before the airway is contaminated by the BAL tube. Many practitioners prefer to obtain TTA samples transendoscopically to avoid percutaneous aspiration. Despite the development of guarded culture swabs for transendoscopic use, this technique does not always prevent contamination of lower airway fluid samples. One study demonstrated that *Pseudomonas* spp. and anaerobic bacteria in cultures of tracheal fluid obtained transendoscopically should be viewed as potential contaminants.[12]

Cytologic evaluation of the TTA/BAL, indicating an increase in polymorphonuclear leukocytes (PMNs), is consistent with parenchymal disease. Some PMNs may be degenerate. Although some clinicians feel that PMNs may be seen in the tracheal aspirates of normal horses, few PMNs are found in bronchoalveolar lavage

fluids from healthy horses (4.4 ± 3.3 cells to 8.9 ± 1.2 cells/μl).[13] How well the results of cytologic evaluation of BAL fluids represent the environment of the lower airways is a matter of some debate. Bronchoalveolar lavage fluids are harvested from a focal area of the lung. If parenchymal disease is not generalized, bronchoalveolar lavage may miss the diseased region. Results of BAL fluid analysis are normal in some horses with pneumonia and pleuropneumonia. Transtracheal wash fluid consists of secretions from both lungs, and TTA cytologic examination was abnormal in all horses with pneumonia and pleuropneumonia in one study.[14] The prevalence of PMNs in TTA fluid from horses without lower respiratory tract disease has not been determined.

145
147

Figure 3.8-2 Approach to cough. *EHV1, 4,* Equine herpesvirus 1 or 4.



The presence of degenerate PMNs and extracellular or intracellular bacteria in TTA/BAL fluid is consistent with the diagnosis of a septic process. The clinician should evaluate a Gram stain to guide the initial choice of antimicrobial agents while awaiting results of culture and sensitivity determinations. Growth of aerobic or anaerobic bacteria in a culture of TTA fluid confirms the presence of bacterial pneumonia if clinical and radiographic findings are also consistent with this disease process. Contamination of cultures of airway secretions obtained via TTA occasionally may occur. Lack of growth of bacterial pathogens from TTA fluid suggests that viral, interstitial, or fungal pneumonia might be present. These possibilities should be investigated by evaluating paired serum samples taken 10 to 14 days apart for influenza virus, equine herpesvirus 1 (EHV1), EHV4, rhinovirus, and equine viral arteritis. Serologic testing for histoplasmosis, blastomycosis, coccidioidomycosis (southwestern United States especially), and possibly mycobacteria should be evaluated. Fungal cultures of tracheal fluid should be evaluated when other more common causes of pneumonia have been ruled out and if the clinical signs of the patient are consistent with this diagnosis. Negative results on serologic tests and fungal cultures in patients with a significant interstitial pattern on thoracic radiographs should prompt consideration of the diagnosis of interstitial pneumonia, a condition for which the inciting cause has not been established and for which the prognosis is grave.

Percussion, radiographic, or ultrasonic evidence of increased intrapleural fluid is an indication for thoracocentesis. Many horses with bacterial pleuropneumonia have elevated pleural fluid PMN concentrations, and PMNs may be degenerate. Intracellular or extracellular bacteria may be seen on cytologic evaluation. Occasionally, frankly neoplastic cells may be identified in thoracic fluid (usually squamous cells or lymphocytes). Many cytologists are uncomfortable diagnosing thoracic neoplasia based solely on an evaluation of pleural fluid. Thoracic fluid should be cultured aerobically and anaerobically. A positive culture identifies the cause of bacterial pleuritis; however, often pleural fluid cultures may be negative. Cultures of TTA fluid are more likely to be positive in horses with pleuropneumonia, and TTA cultures should be performed routinely for these patients. Primary viral pleuritis, although rare in the author's experience, has been reported in horses, and paired serologic examinations for influenza virus and EHV1/EHV4 may be helpful when cultures are negative. One case of pleuritis caused by *Mycoplasma felis* has been reported.[15] Culture of pleural fluid and paired serologic examinations for this organism should be performed in patients for which other tests have not proved diagnostic.

Intrathoracic neoplasms may cause cough with or without accompanying fever. Confirmation of a thoracic tumor may require an ultrasound-guided biopsy or an exploratory thoracotomy and a biopsy. Secondary bacterial pleuritis may complicate thoracic neoplasms, and aerobic and anaerobic cultures of thoracic fluid from patients suspected of having thoracic neoplasms should be performed.

Some febrile coughing horses have no abnormalities on auscultation, percussion, thoracic radiography, or ultrasound. In such patients, occult pulmonary disease may be present and TTA/BAL and culture of TTA fluid are indicated. Alternatively, such horses may have upper airway disease (sinusitis, sinus tumor, guttural pouch empyema), and an endoscopic evaluation is also indicated.

3.8.5.2 COUGH WITHOUT FEVER

When auscultation of the thorax demonstrates primarily expiratory crackles and wheezes, thoracic percussion often reveals a caudoventral expansion of the lung borders. These findings suggest that COPD may be present. Thoracic radiographs usually show increased interstitial densities; radiographs are useful to rule out occult underlying pulmonary disease (such as a well walled-off abscess) but are not required for diagnosis in most cases. TTA and BAL are indicated. Horses with COPD usually have an increase in well-preserved PMNs, and sometimes eosinophils, in TTA and BAL fluids. Growth of pathogens in aerobic or anaerobic culture of TTA fluid identifies secondary bacterial infection. No growth in cultures of TTA fluid is also consistent with the diagnosis of COPD. Occasionally, TTA/BAL fluids may contain parasite larvae or many eosinophils. If horses historically have been housed with donkeys or mules, one should suspect *Dictyocaulus arnfieldi* infestation. Coughing horses younger than 18 months of age with eosinophilic TTA fluid may be experiencing an aberrant migration of *Parascaris equorum* larvae. The clinician should attempt to identify the larvae, although this may be difficult. A direct cytologic evaluation of unfixed, unstained, or iodine-stained mucus may be helpful to identify larvae of *D. arnfieldi*. The clinician should perform a Baermann flotation on feces from the patient and potential reservoir hosts, but the test may not demonstrate ascarid larvae, because pulmonary migration may occur early in the prepatent period.[16] The diagnosis of pulmonary ascarid migration is based on ruling out other causes of pneumonia.

When TTA/BAL fluids have no abnormal cells, cultures still should be assessed. For afebrile coughing horses 147
with thoracic auscultation findings of inspiratory crackles and wheezes and cardiac murmur or arrhythmia, one 148
should take thoracic radiographs. The presence of diffuse pulmonary infiltrates in a bronchoalveolar pattern suggests that pulmonary edema may be present. A complete ultrasonic evaluation of the heart is indicated.

Some coughing, afebrile horses have no abnormalities on auscultation or percussion, and endoscopy of the upper airway and trachea is indicated. Some horses have endoscopic evidence of exudate in the trachea and likely have low-grade COPD. The clinician should take thoracic radiographs of these horses if possible and perform TTA/BAL testing followed by culture of TTA fluid. A transtracheal aspirate should not be obtained immediately after tracheoscopy because bacteria on the endoscope may contaminate airway cultures.

In other patients, cough may be a symptom of upper airway obstructive disease (dorsal displacement of the soft palate, rostral displacement of the palatopharyngeal arch, arytenoepiglottic fold entrapment, subepiglottic cyst, arytenoid chondritis/chondrosis, laryngeal hemiplegia, or tracheal stenosis, collapse, or partial obstruction) or maxillary or frontal sinusitis with discharge into the nasal passages via the nasomaxillary opening or laryngeal/pharyngeal paresis. The latter may be a symptom of guttural pouch mycosis, empyema, or systemic disease (e.g., botulism or equine protozoal myelitis). Cough also may be a symptom of a tracheal foreign body (e.g., a twig or TTA catheter) in the airway. One should suspect horses with cough but no abnormalities on endoscopic examination of having low-grade COPD.

Cough after exercise or feeding also should prompt an endoscopic evaluation. Evidence of hemorrhage in the trachea after exercise indicates that exercise-induced pulmonary hemorrhage is likely. This diagnosis can be confirmed by finding hemosiderin-laden macrophages in BAL or TTA fluid. Thoracic radiographs may show interstitial densities and pleural thickening in the caudodorsal lung field. Postprandial cough may be associated with soft palate paresis, dorsal displacement of the soft palate, cleft palate (neonates and foals), or dysphagia of any cause.

A detailed description of diagnostic and therapeutic strategies for diseases of the respiratory system can be found in Chapter 7.

3.9—Changes in Body Temperature

Melissa T. Hines

Assessment of body temperature is an essential part of every physical examination. As with all mammalian species, 148

horses normally maintain their core body temperature within a narrow range despite extremes in environmental 149 conditions. The core temperature may vary by approximately 1° C (2° F) between individuals. In adult horses, the average normal body temperature is 38.0° C (100.5° F), whereas in neonatal foals the temperature tends to be slightly higher, ranging from 37.8° to 38.9° C (100.0° to 102.0° F). A diurnal variation of up to 1° C (2° F) may occur, with the low point typically in the morning and the peak in the late afternoon.

3.9.1

Control of Body Temperature

The set-point is the crucial temperature that the body attempts to maintain, primarily via neuronal control operating through temperature centers in the hypothalamus.[1,2] Peripheral and central thermoreceptors sense changes in ambient and core body temperatures and activate feedback mechanisms that bring the temperature back to the set-point. Specifically, the anterior hypothalamic-preoptic area contains large numbers of heat-sensitive neurons and lower numbers of cold-sensitive neurons that function as temperature detectors. Peripheral receptors, which are generally most sensitive to low temperatures, are located in the skin and in some deep tissues, such as the spinal cord, abdominal viscera, and around certain great veins. The anterior hypothalamic-preoptic area and the peripheral receptors transmit signals into the posterior hypothalamic area, subsequently activating autonomic and behavioral effector responses to regulate body temperature.

When the body temperature is too high, heat loss increases and heat production diminishes. Increasing blood flow to the skin is an effective mechanism for heat transfer from the body core to the surface. In response to changes in core body temperature and environmental temperature, the sympathetic nervous system regulates the degree of vasoconstriction and thus the amount of blood flow. Heat is lost from body surfaces to the surroundings by several physical mechanisms, including radiation, conduction, and convection. Evaporation is

also an important mechanism of heat loss in horses.[3] The rate of sweating controls to some extent the amount of evaporative heat loss. However, even when the animal is not sweating, water evaporates insensibly from the skin and lungs, causing continual heat loss. In horses, evaporative heat loss, primarily though increased sweating but also through increased respiration, becomes more important as the ambient temperature rises and during exercise.[3,4] In addition to increased heat loss when the body temperature rises, the horse also decreases temperature further by inhibiting means of heat production, such as shivering, and by behavioral responses, such as seeking shade, wind currents, and wading into water.

Mechanisms that increase body temperature come into play when the body temperature is too low.[2] Heat is conserved by stimulation of the posterior hypothalamic sympathetic centers leading to cutaneous vasoconstriction and piloerection. Heat production also increases and may occur through increased muscle activity ranging from inapparent contractions to generalized shivering. Shivering may increase heat production by 4 to 5 times baseline. The primary motor center for shivering is in the posterior hypothalamus, which normally is stimulated by cold signals from the peripheral receptors and to some extent the anterior hypothalamic-preoptic area. Signals from heat sensitive neurons in the anterior-hypothalamic-preoptic area inhibit the center. Digestion of food also contributes to total body heat. Sympathetic stimulation may increase the rate of cellular metabolism, increasing heat production by chemical thermogenesis. Cooling also increases the production of thyrotropin-releasing hormone, ultimately increasing thyroid hormones and cellular metabolism, and further contributing to chemical thermogenesis. In addition to these physiologic adaptations, behavioral responses to conserve heat also occur, such as adopting a huddled stance, aggregating in groups, and seeking shelter.

3.9.2 Conditions of Increased Body Temperature

Elevation of the body temperature above normal is one of the most common clinical problems encountered, and although classically associated with infection, a variety of disorders may cause increased body temperature. One should distinguish between conditions of hyperthermia, in which the temperature set-point is unaltered, and true fever, in which the set-point actually increases.

3.9.2.1 HYPERTHERMIA

The body temperature may become elevated without an increase in the set-point when a loss of equilibrium occurs in the heat balance equation. Increased heat production or absorption of heat beyond the ability of the body to dissipate heat may occur. In some conditions, impaired heat loss also may occur. Hyperthermic conditions include problems such as exercise-related hyperthermia, heat stroke, malignant hyperthermia, anhidrosis, central nervous system disorders, and reactions to certain toxins or drugs. In general, these conditions do not respond to treatment with antipyretic drugs.

3.9.2.2 EXERCISE-RELATED HYPERTHERMIA

During sustained or high-intensity exercise, increased heat production is associated with muscular activity.[3,4]
The heat produced may exceed the ability of the body to lose heat, resulting in an increased core body 149
temperature. Typically, the temperature returns to normal with rest as heat loss mechanisms remain activated. 150
Elevated temperature also may occur with the intense muscle activity associated with generalized seizures.

3.9.2.3
HEAT STROKE

Heat stroke occurs when the body temperature rises above a critical temperature, leading to multisystemic problems. In horses, signs of heat stroke may develop when the body temperature is above 41.5° C (107° F), which most often occurs in association with exercise in environmentally stressful conditions. Although horses can acclimatize to various weather conditions to some extent, the efficiency of evaporative heat loss may be compromised significantly in hot, humid weather.[4,5] Susceptibility to heat stroke may increase if sweating leads to dehydration and electrolyte imbalances. Once the body temperature reaches the critical point, the homeostatic mechanisms of thermoregulation fail, resulting in peripheral vasoconstriction, decreased cardiac output, and decreased blood pressure. Affected horses are lethargic, with weak flaccid muscles. Prostration, circulatory shock, disseminated intravascular coagulation, multiple organ failure, and death may occur.

3.9.2.4
ANDHIDROSIS

Especially in hot, humid climates, horses may develop anhidrosis, which is characterized by a partial or total loss of the ability to sweat.[6] Because of the resulting impaired heat loss, hyperthermia may develop. Clinical signs of poor performance, increased respiratory rate, and poor hair coat also are observable.

3.9.2.5
MALIGNANT HYPERTHERMIA

Malignant hyperthermia encompasses a group of inherited skeletal muscle disorders in which calcium metabolism is altered.[7] Although the condition is most common in human beings and pigs, it has been reported in several species, including horses.[8,9] The disorder is characterized by a hypermetabolic state of muscle that generally is induced by halogenated inhalation anesthetics, depolarizing skeletal muscle relaxants, and occasionally local anesthetics or stress. Clinical signs include a rapid increase in core body temperature, skeletal muscle rigidity, and tachycardia. Affected animals may develop significant acidosis and muscle necrosis and in some cases may die. In pigs, malignant hyperthermia has been linked to a single point mutation in the gene for the skeletal muscle ryanodine receptor, but a genetic basis has not yet been established in horses.[7]

3.9.2.6
CENTRAL NERVOUS SYSTEM DISORDERS

Any condition affecting those areas of the hypothalamus involved in thermoregulation may alter the body temperature, with hyperthermia being more common than hypothermia.[1,2] Thus central hyperthermia occurs in association with a variety of conditions, including hemorrhage, neoplasms or abscesses, infectious/inflammatory changes, and degenerative disorders. Central hyperthermia usually is characterized by a lack of any diurnal variation, absence of sweating, resistance to antipyretic drugs, and excessive response to external cooling.

3.9.2.7
CERTAIN TOXINS OR DRUGS

Occasionally, hyperthermia has been associated with toxins or drugs. Exposure to compounds that act to uncouple oxidative phosphorylation, such as the wood preservative pentachlorophenol, potentially could cause a significant rise in body temperature.[10] Foals treated with the antibiotic erythromycin are at risk of

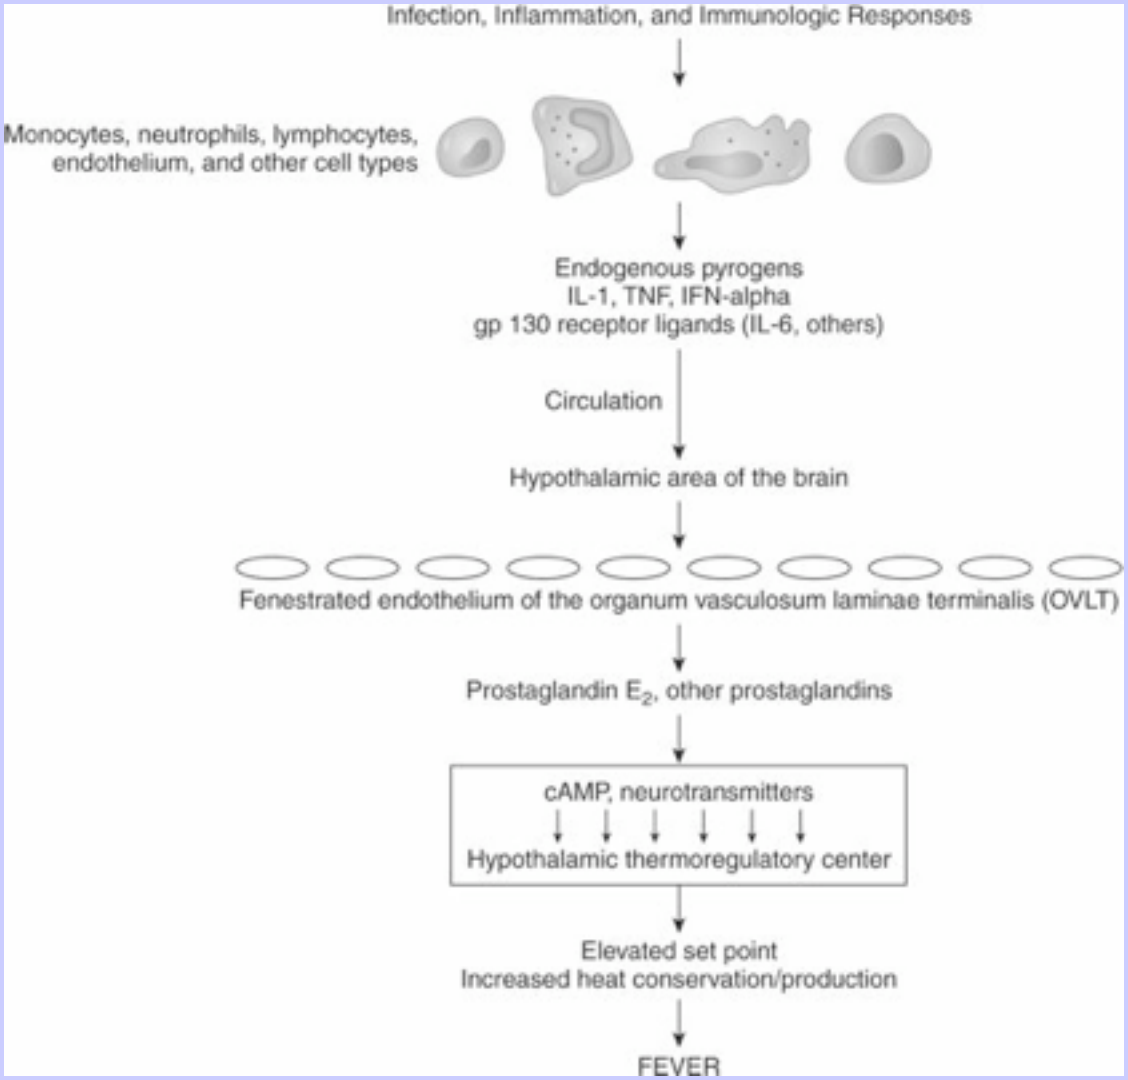
developing hyperthermia.[11] Such predisposition has been attributed to a reaction to the erythromycin itself or to an alteration of the thermoregulatoy system of the foal by mechanisms not yet described. Environmental conditions may exacerbate the development of hyperthermia, with foals exposed to high ambient temperatures and direct sunlight being at greatest risk.

3.9.3 Pathogenesis of True Fever

In true fever the set-point for the desired core body temperature increases and then is maintained by the same mechanisms that maintain the normal body temperature. Although primarily associated with infectious diseases, fever is also a prominent component of many inflammatory, immunologic, and neoplastic conditions. Although the pathogenesis of the febrile response is complex, essentially all of these conditions initiate fever by stimulating the release of endogenous pyrogens (Figure 3.9-1).

Endogenous pyrogens are substances with the biologic property of fever induction.[12,13] Initially endogenous pyrogen was assumed to be a single molecule produced by leukocytes, thus the name leukocytic or granulocytic pyrogen. Now, multiple cytokines are known to act as pyrogens, and a variety of cell types produce them, with monocytes and macrophages predominating. Currently, the following cytokines are thought to be intrinsically pyrogenic in that they produce a rapid-onset fever via direct action on the hypothalamus without requiring formation of another cytokine: interleukin-1α (IL-1α) and IL-1β, tumor necrosis factors (TNF) α and β, interferon-α, and IL-6. IL-1α and IL-1β and TNF-α appear to be among the most potent pyrogens. Many endogenous pyrogens use the cell-signaling apparatus gp130. Cytokines that act through this receptor include
IL-6, IL-11, oncostatin M, ciliary neurotrophic factor, cardiotropin-1, and leukemic inhibitory factor. From a 150
clinical standpoint, several pyrogenic cytokines are produced during most febrile diseases and contribute to the 151
febrile response.

Figure 3.9-1 Schematic representation of the pathogenesis of fever. *cAMP,* Cyclic adenosine monophosphate; *IFN,* interferon; *IL,* interleukin; *TNF,* tumor necrosis factor.



The precise mechanism of action of pyrogenic cytokines in the central nervous system is still unclear. Endogenous pyrogens probably act on the circumventricular organs or organum vasculosum laminae terminalis (OVLT), a rich vascular network associated with neurons of the preoptic anterior hypothalamus.[13–15] Ablation of the OVLT prevents fever after a peripheral injection of endogenous pyrogens but has no effect when endogenous pyrogens are injected directly into the brain tissue.[14] In the region of the OVLT the blood-brain barrier is minimal, and endothelial cells lining this region may allow direct movement of endogenous pyrogens into the brain or they may release arachidonic acid metabolites in response to endogenous pyrogens, which then move into the brain. The production of arachidonic acid metabolites, particularly prostaglandin E_2 via the cyclooxygenase 2 (COX-2) pathway is clearly important in the pathogenesis of fever, because COX inhibitors,

and specifically COX-2 inhibitors, effectively reduce the febrile response but have no effect on the normal body temperature. The prostaglandins do not act directly but initiate neuronal signaling by producing a cascade of changes in cyclic nucleotides, calcium, and monoamines leading to a higher set-point in the hypothalamic thermoregulatory center.

Physiologic mechanisms exist to control the febrile response and prevent extremes that are incompatible with life. Multiple feedback mechanisms limit the activity of the pyrogenic cytokines and many endogenous cryogens or antipyretics have been identified.[16,17] For example, IL-10, which can be induced by pyrogenic cytokines, inhibits further production of IL-1 and TNF. Arginine vasopressin and α-melanocyte-stimulating hormone act within the brain to decrease fever.[16–19] When administered to human beings, α-melanocyte-stimulating hormone is a much more potent antipyretic than acetaminophen. Nitric oxide also has been shown to have an antipyretic role, mediated by cyclic guanosine monophosphate, in the anterior hypothalamic-preoptic region.[20] 151

152

The cytokines that act as endogenous pyrogens have a variety of biologic effects. Therefore the onset of fever is accompanied by several hematologic, immunologic, and metabolic changes referred to as the acute phase response. In particular, IL-6 and IL-11 induce the synthesis of acute phase proteins by hepatocytes, including fibrinogen, C-reactive protein, haptoglobin, and others. Similarly, hypoferremia, hypozincemia, and hypercupremia are cytokine mediated, as is the activation of lymphocytes, which in turn produce additional cytokines.

Pyrogenic cytokines, particularly IL-1 and TNF-α cause membrane perturbation with an increase in phospholipases and the production of arachidonic acid.[12,13] The subsequent production of mediators depends on the metabolic pathways for arachidonic acid in the target tissue. Prostaglandins induced by endogenous pyrogens stimulate the muscle catabolism associated with fever and induce collagenase synthesis from synovial cells, contributing to the muscle and joint pain often seen with fever. Local tissue responses to IL-1β and TNF-α may stimulate afferent neural impulses that lead to behavioral responses associated with fever, such as lethargy and anorexia. As expected, treatment with COX inhibitors can diminish many of the signs of fever.

3.9.4 Effects of Fever

Fever is a normal physiologic response with beneficial and adverse effects to the animal. With the exception of some viral infections, the elevation in temperature is generally not high enough to affect pathogens directly. However, studies on bacterial infections in several species have demonstrated an increase in survival with fever, which is thought to be caused primarily by enhanced host defenses.[21–23] In addition, the concentration of iron, which is required by many bacteria for multiplication, decreases during the acute phase response.[24–26] If the temperature becomes extremely high, many of the beneficial effects are reversed.[2,27,28] In rabbits the severity of bacterial infection increases when the body temperature in more than 3° C (5° F) above normal. The increased catabolism, variable anorexia, and increased metabolic rate can lead to muscle wasting and weakness when fever is prolonged. Although seizures induced by fever are uncommon in horses, they can be seen in neonates when the temperature is above 42° C (108° F).[29] In debilitated animals, prolonged fever has been associated with cardiovascular failure.

3.9.5 Approach to Fever

Increased body temperature is a common clinical sign with diverse causes (Figure 3.9-2). Fortunately, in many cases the cause may be readily apparent based on the signalment, history, and physical examination. Conditions

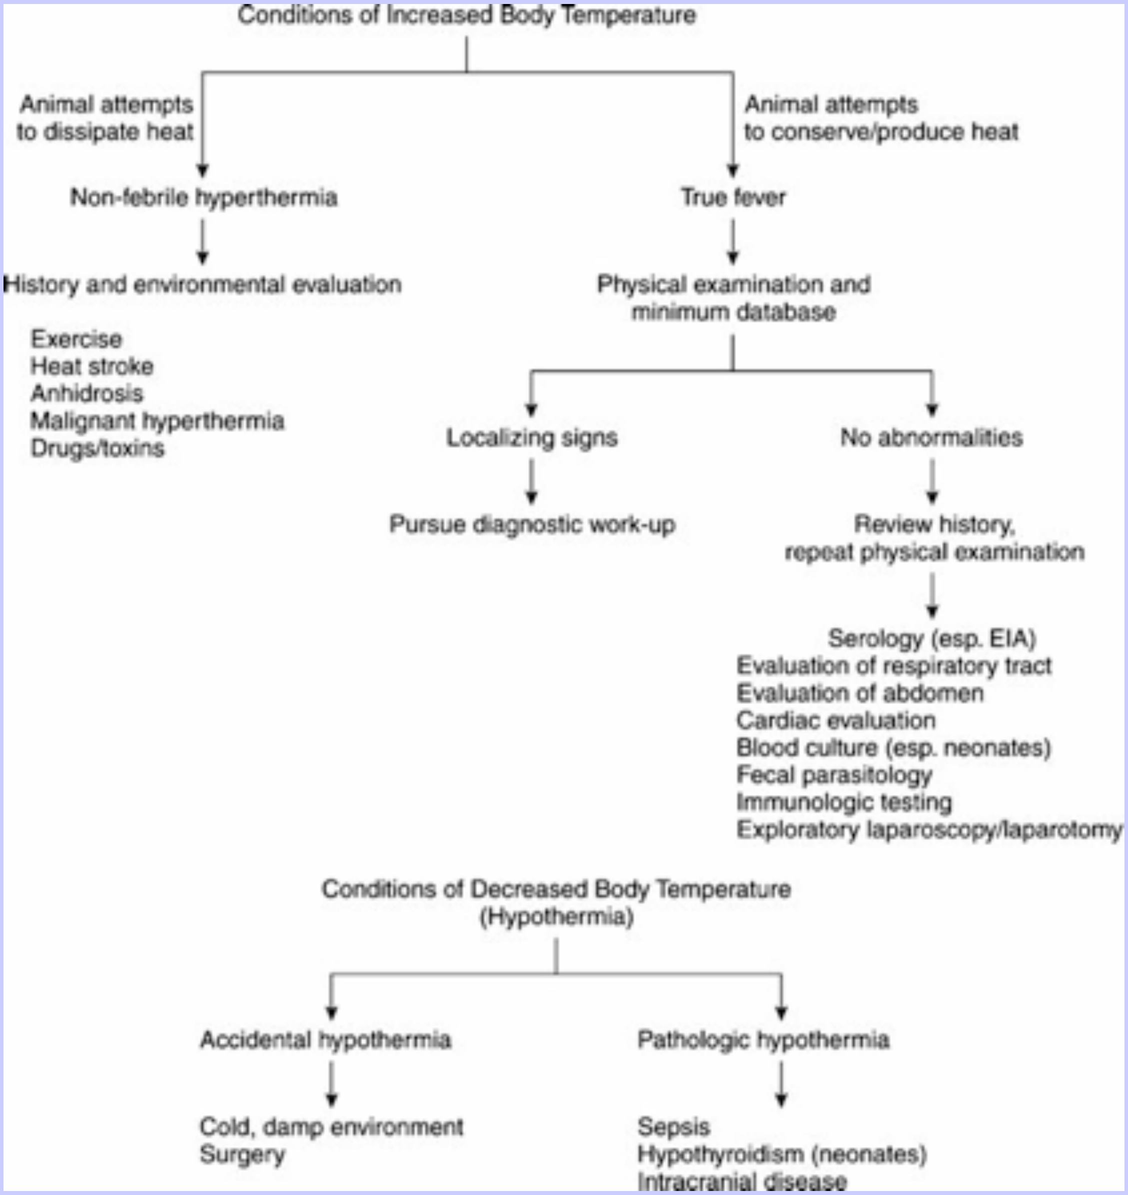
of increased temperature such as exercise-related hyperthermia and malignant hyperthermia are often apparent from the history. Infectious diseases remain the most common cause of fever, and often localizing clinical signs such as nasal discharge or diarrhea aid in the diagnosis. In other cases, an increased temperature may be one component of another obvious condition, such as neoplasm, immune-mediated disease, or a drug reaction.

3.9.6 Fever of Unknown Origin

Fever of unknown origin exists when fever is prolonged with no other specific signs. In many cases, the cause is a common disease with an unusual presentation. The specific criteria used to define fever of unknown origin in the horse in a review of 63 cases included the following: (1) illness of at least 3 weeks' duration associated with nonspecific signs, (2) body temperature of at least 38.6° C (101.5° F) on several occasions, and (3) no clear diagnosis after an initial complete blood count and serum biochemical profile.[30] The most common cause was found to be infection, which was responsible for 43% of the cases. Other causes included neoplasms in 22% of cases, immune-mediated diseases in 6.5%, and miscellaneous diseases including toxic hepatopathy, parasitism, and others in 19%. In 9.5% of cases, no diagnosis was made. Therefore diagnosis of fever of unknown origin requires a systematic approach with emphasis on the evaluation of infectious disease.

The clinician can have the body temperature taken twice daily over a period of time to document fever and identify any pattern. Although some inconsistencies in the precise terminology used to define patterns of fever exist, *intermittent fevers* generally are characterized by recurring paroxysms of elevated temperature followed by periods of normal temperature, such as those fevers that demonstrate diurnal variation. Intermittent fevers most often are associated with infectious causes, particularly viral infections, although they may be seen with a variety of other conditions. In most cases of intermittent fever the temperature tends to peak in the late afternoon or evening, though this is not always the case. *Remittent fevers* are those in which diurnal variation is exaggerated without a return to normal body temperature or those with a cyclic pattern in which the temperature elevation lasts for several days, such as may be seen with equine infectious anemia virus. *Biphasic fevers,* in which an initial rise in body temperature precedes a period of normal temperature and then a second rise, are characteristic of certain diseases such as equine monocytic ehrlichiosis (Potomac horse fever). Sustained fevers are those in which the elevation of temperature is consistent. 152

Figure 3.9-2 Approach to changes in body temperature.



A complete history is important when one is investigating fever of unknown origin. Any exposure to *Streptococcus equi* ssp. *equi* (strangles) may be significant because of the association of this organism with internal abscessation. Travel history may be relevant, especially regarding diseases with a geographic influence such as babesiosis and coccidioidomycosis.

The clinician always should perform a careful physical examination, including rectal palpation. Repeating the physical examination may yield new information. The clinician also should perform a complete neurologic examination, because disorders of the central nervous system may cause aberrations in temperature through pyrogenic cytokines or in some cases through direct effects on thermoregulatory centers.

Ancillary diagnostic tests usually are required to diagnose fever of unknown origin. A minimum database, including complete blood count, fibrinogen, biochemical profile with bile acids, and urinalysis should be performed. Hemoparasites occasionally may be seen on the blood smear, but the apparent absence of organisms does not rule out a parasitemia that is below readily detectable limits. Abnormalities consistent with chronic infection or inflammation, including anemia, hyperfibrinogenemia, and hyperglobulinemia are common but nonspecific findings. If an elevation of serum protein occurs, further assessment by serum protein electrophoresis and specific immunoglobulin quantitation may be indicated. A monoclonal gammopathy is characteristic of plasma cell myeloma and other tumors of the reticuloendothelial system, both of which may initiate fever directly and increase susceptibility to bacterial infection. In general, immunodeficiencies may be associated with chronic infections. If the serum protein is low, one should investigate the causes of hypoproteinemia, including 153
decreased production because of significant hepatic disease, increased gastrointestinal or renal loss, or loss into a 154
third space. The presence of hypercalcemia can be helpful in establishing a diagnosis, because in horses, hypercalcemia most often is linked with renal disease or neoplasms.

Infections of the respiratory tract and abdomen frequently are associated with fever of unknown origin in the horse, and therefore one should evalute these systems thoroughly. Careful auscultation of the thorax using a rebreathing bag should be performed at rest and, if possible, after exercise. Endoscopy, including examination of the guttural pouches can be useful. Diagnostic imaging of the thorax, including radiographs and ultrasound, often is indicated. The clinician also should include thoracocentesis in evaluation of the thorax, for abnormalities occasionally are apparent even without increases in the volume of pleural fluid. Pleuroscopy, which allows direct visual examination of the pleural space and which may facilitate biopsy of any masses, can be helpful in establishing a diagnosis, especially when neoplasia is suspected.

Peritonitis and abdominal abscessation are common causes of fever of unknown origin, and one should include abdominocentesis in the diagnostic plan. The peritoneal fluid should be evaluated for protein, cellularity, and cell morphology, and culture should be performed. One should remember that although many neoplastic conditions involve the abdomen, neoplastic cells are not always observed in the peritoneal fluid. In cases of gastric squamous cell carcinoma, gastroscopy is helpful in establishing the diagnosis. Radiographs of the abdomen may be useful, especially in neonates, and ultrasound of the abdomen may help to identify fluid for collection or abnormalities that indicate further evaluation, such as abdominal masses or pathologic liver conditions.

Gastrointestinal parasitism is a common clinical problem in the horse, although it is associated only occasionally with fever. However, one should examine feces for parasite ova in horses with fever of unknown origin. In cases of suspected gastrointestinal protein loss, diarrhea, or melena, one should consider diagnostic procedures such as fecal culture, polymerase chain reaction for *Salmonella,* rectal mucosal biopsy, or absorption tests.

Bacterial endocarditis can cause a fever of unknown origin, although the condition is not as common in horses as in some other species. In the study by Mair, Taylor, and Pinsent, the authors identified endocarditis in 3 of 63 cases of fever of unknown origin.[30] In each case a murmur they did not identify initially became apparent several weeks after the onset of illness. Therefore a thorough cardiac evaluation, including echocardiography, is indicated.

Blood cultures are generally most useful in neonates but can yield valuable information in adult horses with fever as well. Ideally, one should collect three to five samples at least 45 minutes apart when the horse is not in a regimen of antibiotic therapy. Sampling just before and during a temperature rise is most likely to yield a positive culture.

The clinician should consider equine infectious anemia as a differential diagnosis for horses with fever of unknown origin and should perform a serologic examination. Recently, a serologic test for detection of antibodies to the M protein of *Streptococcus equi* ssp *equi* was developed as an aid in the diagnosis of internal abscessation.[31] Serologic tests for equine babesiosis, brucellosis, and coccidioidomycosis are also available.

Immune-mediated disorders such as autoimmune hemolytic anemia, immune-mediated thrombocytopenia, systemic lupus erythematosis, vasculitides, and rheumatoid arthritis have been implicated as causes of fever of unknown origin, but more commonly in human beings and small animals than in horses. However, appropriate diagnostic tests, such as the Coombs' test, skin biopsy, and antinuclear antibody testing may be useful in some cases.

Exploratory laparoscopy or laparotomy is indicated when abdominal involvement is evident or the animal is becoming progressively debilitated. Occasionally, bone marrow aspiration may be useful, particularly in those cases with persistent abnormalities in circulating cell populations. In cases in which a specific diagnosis has not been made, therapeutic trials with antimicrobials may help, and in cases of suspected immune-mediated disease, corticosteroids may help.

3.9.7 Hypothermia

Hypothermia occurs when the core body temperature drops below accepted normal values. In clinical cases, hypothermia can be characterized as accidental or pathologic (see Figure 3.9-2). In accidental hypothermia a spontaneous decrease in the core body temperature occurs independent of actual disruption to the thermoregulatory system. These cases often can be identified from the history. Mild accidental hypothermia sometimes occurs with surgical procedures. Most often, accidental hypothermia is associated with exposure to cold or cold, damp environments, which can lead to severe hypothermia and death. Neonates are particularly susceptible to hypothermia, although central thermoregulation through the hypothalamus is normal.[32,33] Sick foals often decrease their activity and nutritional intake and have alterations in circulation. They also have a large ratio of surface area to body weight, enhancing heat loss. Geriatric and otherwise debilitated animals are also at increased risk of hypothermia.

One should consider pathologic causes of hypothermia when no clear reason for accidental hypothermia is evident. Pathologic hypothermia occurs in association with disorders that decrease metabolic activity or directly affect the thermoregulatory center and occurs with endocrine disorders, sepsis, and intracranial disease. In horses, hypothyroidism is probably an uncommon clinical problem; however, impaired thermoregulation has been seen in foals with congenital hypothyroidism.[34] Lesions of the thyroid gland also have been associated with hypothermia in donkeys.[35] Hypothermia has been observed with septicemia and shock, especially in neonates, in which 24% of septic foals were found to have a decreased body temperature.[36] 154 155

The ability to generate heat through shivering is impaired or lost when the body temperature becomes too low. The animal experiences a decrease in the metabolic rate of most tissues. Heart rate, cardiac output, glomerular filtration, and blood pressure may decrease.

3.10—Diarrhea

Melissa T. Hines

Diarrhea, defined as an increase in the frequency, fluidity, or volume of bowel movements, is a commonly encountered clinical problem in the horse. Diarrhea may occur as a primary disease of the gastrointestinal tract or as a secondary response to another disease process, such as sepsis, endotoxemia, or hepatic disease.

The function of the equine gastrointestinal tract is complex and involves maintenance of normal fluid balance and digestion and absorption.[1–3] As a result of dietary intake and endogenous secretions, normally a large volume of fluid enters the gastrointestinal tract, most of which is reabsorbed. In the adult horse absorption occurs predominantly in the large bowel, where a volume of water approximately equal to the total extracellular fluid volume of the animal, or about 100 L, is recovered during the course of the day. Because the large colon is the primary site of water resorption, most significant diarrheal disease in the adult horse involves the colon. In young foals, however, small intestinal disorders such as rotaviral infection also may result in diarrhea.[4]

A second critical function of the large bowel is that of microbial digestion of carbohydrates and, to some extent, protein or nonprotein nitrogen.[1–3] Microbial fermentation of carbohydrates in the cecum and colon results primarily in the production of volatile fatty acids, which are absorbed readily, providing up to 75% of the energy requirement of the horse. Therefore maintaining a stable environment for the microbial population is important. In general, efficient function of the large bowel requires mechanisms that limit the rate of digesta passage, provide optimal conditions for microbial digestion, and allow for efficient transport of solutes and water.

The characteristics of normal equine feces vary somewhat with diet. Generally, equine feces are tan, brown, or greenish, and although approximately 75% water, they are well formed. An adult horse on a diet of grass hay and approximately 3 lb of oats per day produces about 20 to 28 g of feces per kilogram of body mass per day or about 11 to 13 kg of feces per day.[5] In cases of diarrhea, the amount of feces may increase up to tenfold, with horses producing more than 200 g/kg/day, or more than 90 L of diarrhea. As a result, diarrhea can cause significant losses of electrolytes and water and significant systemic acid-base imbalances. However, despite large water losses, horses with chronic diarrhea seldom develop severe dehydration or electrolyte abnormalities because they compensate for increased fecal losses.

3.10.1 Mechanisms of Diarrhea

Inflammation within the bowel plays a central role in the pathogenesis of diarrhea. Several basic mechanisms of diarrhea have been described, and in most diarrheal diseases, more than one mechanism is involved. These mechanisms include the following:

1. *Malabsorption:* Malabsorption results from a decrease in the functional absorptive surface area of the gastrointestinal tract. Villus atrophy in the small intestine, seen with rotaviral enteritis and infiltrative bowel disease, can result in malabsorption because of the loss of functional epithelium and maldigestion caused by decreased production of digestive enzymes. A number of insults to the colon result in inflammation and disruption of absorptive cells and tight junctions, leading to decreased absorptive capacity and decreased ability to retain absorbed fluid, that is, increased loss. Several inflammatory mediators, such as histamines and prostaglandins, contribute to the colonic inflammation. These mediators are produced primarily by inflammatory cells in the lamina propria and inhibit absorption through a variety of mechanisms.[6–10]

2. *Increased secretion:* The increased secretion of solutes and water by the inflamed colon can contribute significantly to the development of diarrhea. Although the precise mechanisms of secretion in the equine colon are not understood fully, active secretion and passive fluid loss occur.[6–12] Control of active secretion is complex, involving two primary pathways: first, the activation of adenyl cyclase, resulting in an increase of intracellular cyclic adenosine monophosphate concentrations, and second, the activation of calcium channels, leading to increased intracellular calcium concentrations.[11,12] Cyclic adenosine monophosphate and calcium stimulate specific secretory activities, primarily through chloride channels. In some cases of diarrhea, bacterial enterotoxins such as those produced by certain strains of *Escherichia coli* and *Salmonella* stimulate adenyl cyclase activity, thus increasing active secretion. This is true hypersecretory diarrhea. Also, a number of inflammatory mediators produced by the inflamed colon, particularly prostaglandin E, increase intracellular concentrations of cyclic adenosine monophosphate and to some extent calcium, thereby increasing active secretion by mucosal cells.[11–13] Inflammation also enhances passive fluid loss through a number of factors, such as changes in hydrostatic pressure in the colonic capillaries, mucosal damage, and loss of tight junctions. In cases of severe mucosal injury, the loss

of protein can decrease vascular oncotic pressure and further potentiate fluid exchange across the endothelium.

156

157

3. *Decreased transit time (abnormal motility):* Progressive motility must be present for diarrhea to occur. Primary motility disorders causing diarrhea are not well recognized, although diarrhea associated with stress or excitement may represent this phenomenon. Inflammation is known to influence gastrointestinal motility, in addition to altering absorption and secretion. However, the precise significance of the altered motility in the pathogenesis of diarrhea is not clear. Sufficient retention time and thorough mixing are required for digestion and absorption of nutrients and fluid to occur, and decreased intestinal transit time has been recognized in association with many gastrointestinal diseases, including infectious diarrhea. Absorption of endotoxin and the release of inflammatory mediators, including prostaglandins, disrupts normal motility patterns.[14] In some cases of acute colitis, a period of ileus may occur without diarrhea. With diarrheal diseases, the elimination of gut contents is part of the normal host defense mechanism, and thus decreasing motility is not indicated in most cases.

4. *Osmotic overload:* Any increase in osmotically active particles within the intestinal lumen can result in diarrhea. The increase can be associated with the administration or ingestion of osmotically active substances such as magnesium sulfate. The increase also may be associated with overloading of the intestine with carbohydrates or occasionally lipids beyond the amount that can be digested and absorbed. Therefore sudden dietary changes that result in significant shifts in gut flora and changes in fermentation or gastrointestinal diseases that result in malabsorption or maldigestion also may result in an osmotic diarrhea. In foals the loss of villus epithelial cells in the small intestine associated with disorders such as rotavirus infection and clostridiosis may lead not only to malabsorption but also to maldigestion caused by the decreased production of lactase.[4,15] The resulting lactose intolerance allows excess lactose to enter the large intestine, increasing the osmotic load.

5. *Increased hydraulic pressure from the blood to the lumen:* This mechanism of diarrhea is more common in chronic conditions, such as congestive heart failure or inflammatory bowel disease. The condition may result from decreased oncotic pressure associated with hypoproteinemia, increased capillary hydrostatic pressure (as in heart failure), or decreased lymphatic drainage associated with inflammation of lymphatics and lymph nodes.

Understanding the mechanisms of diarrhea can be helpful in directing therapy. However, one must remember that most disorders that cause diarrhea, whether infectious or noninfectious, do so through inflammatory mechanisms resulting in multiple functional alterations.

TABLE 3.10-1 Differential Diagnoses for Acute Diarrhea in Adult Horses

CAUSES	MAJOR DIAGNOSTIC TEST(S)
COMMON	
Salmonellosis	Fecal culture or polymerase chain reaction (PCR), culture of rectal mucosal biopsy
Potomac horse fever (equine monocytic ehrlichiosis)	PCR (feces, peripheral blood), paired serologic tests
Clostridiosis (*Clostridium difficile, C.perfringens*)	Fecal culture, toxin analysis
Antibiotic-associated diarrhea	History
Nonsteroidal antiinflammatory toxicity (primarily right dorsal colitis)	History and supportive clinicopathologic findings, ultrasonography, exploratory surgery with biopsy
Undiagnosed	Other conditions ruled out
LESS COMMON	
Cantharidin toxicity	
Parasitism (strongylosis, cyathostomiasis, other)	
Aeromonas, Campylobacter	
Sand	
Carbohydrate overload	
Arsenic toxicity, other toxicities	
Thromboembolic disease	
Anaphylaxis	

3.10.2 Diagnostic Approach to the Patient With Diarrhea

Diarrhea is a common, and sometimes fatal, clinical problem of adult horses and foals. A number of specific
causes for acute and chronic diarrhea have been identified (Tables 3.10-1, 3.10-2, and 3.10-3). A comprehensive 157
evaluation may help in establishing a diagnosis and developing a treatment plan (Box 3.10-1). However, even in 158
severe cases a definitive diagnosis often is not made, making the problem particularly frustrating.[16,17]

TABLE 3.10-2 Differential Diagnoses for Chronic Diarrhea in Adult Horses

CAUSE OF DIARRHEA	MAJOR DIAGNOSTIC TEST(S)
Chronic salmonellosis	Fecal culture or polymerase chain reaction, culture of rectal mucosal biopsy
Sand	Fecal sedimentation
Parasitism (strongylosis, cyathostomiasis)	Fecal egg count, empirical deworming
Nonsteroidal antiinflammatory toxicity (primarily right dorsal colitis)	History and supportive clinicopathologic findings, ultrasonography, exploratory surgery with biopsy
Inflammatory or infiltrative disorders	Histopathologic exam, absorption tests (supportive but nonspecific)
Inflammatory bowel disease (granulomatous, lymphocytic-plasmacytic, or eosinophilic enterocolitis)	
Mucosal lymphosarcoma	
Amyloidosis	
Dietary: abnormal fermentation	History
Neoplasms: lymphosarcoma, squamous cell carcinoma	Histopathologic exam
Peritonitis, abdominal abscessation	Peritoneal fluid analysis, ultrasound, exploratory surgery
Nongastrointestinal causes (chronic liver disease, congestive heart failure, renal disease)	Physical exam, clinicopathologic findings

3.10.2.1

HISTORY AND PHYSICAL EXAMINATION

One should consider the signalment and history carefully when evaluating a patient with diarrhea. Age is particularly important because several disorders, such as foal heat diarrhea and rotavirus, are age related. The genetic background also may be significant, because diarrhea has been associated with certain heritable immunodeficiencies, and granulomatous bowel disease has been identified in three sibling horses.[18–20] Establishing whether the diarrhea is acute or chronic is important. Other historical questions of particular relevance include dietary changes, deworming program, involvement of single versus multiple animals, exposure to sand, and the use of medications, especially antibiotics and nonsteroidal antiinflammatory drugs.[21–23] Other concurrent diseases, stress, possible exposure to toxins, weight loss, water consumption, and salt availability also may be significant. The information obtained helps to prioritize differential diagnoses and direct further testing.

TABLE 3.10-3 Differential Diagnoses for Diarrhea in Foals

CAUSE OF DIARRHEA	MAJOR DIAGNOSTIC TEST(S)
Salmonellosis	Fecal culture or polymerase chain reaction (PCR)
Clostridiosis (*Clostridium difficile, C.perfringens*)	Fecal culture, toxin analysis
Endotoxemia, gram-negative septicemia	Blood culture, physical exam, complete blood count, sepsis score
Antibiotic-associated diarrhea	History
Foal heat diarrhea	History, physical exam
Viral: rotavirus; rarely coronavirus or adenovirus	Electron microscopy, enzyme immunoassay
Protozoan: cryptosporidiosis	Fecal analysis
Secondary lactose intolerance	Oral lactose tolerance test, response to therapy
Rhodococcus equi	Culture, PCR
Lawsonia intracellulare	Fecal PCR, serologic testing
Gastric ulcer disease syndrome	Gastric endoscopy
Strongyloides westeri	Fecal egg count
Sand	Fecal sedimentation

The clinician should perform a complete physical examination. The body condition of the horse and the presence of any edema should be noted. The presence of fever, dehydration, or signs of endotoxemia may help in assessing the severity of the disease and differentiating the cause, because some causes of diarrhea are not associated typically with systemic signs of illness. Careful evaluation of the abdomen should be performed. Visible abdominal distention is often an indication of large intestinal distention, which may occur in 158
association with acute colitis. However, distention also may be visible with extreme dilation of multiple loops 159
of small intestine. Careful auscultation of the abdomen can be useful in assessing motility. Generally, progressive borborygmi heard about every 3 to 4 minutes on both sides of the abdomen suggests normal motility of the cecum and colon. Auscultation behind the xiphoid process may help to identify the presence of sand or gravel if one hears particles grinding together during contractions of the colon.[24] Particularly in foals, transabdominal palpation and ballottement may be useful to identify increased abdominal fluid or large masses near the body wall. Transrectal palpation can be helpful in assessing the size of intestinal segments, consistency of contents, and wall thickness as well as in identifying masses, enlarged lymph nodes, or mesenteric arteritis.

3.10.2.1.1

BOX 3.10-1 OUTLINE OF DIAGNOSTIC APPROACH TO DIARRHEA

I. Signalment, history, and physical examination

II. Clinical pathology

1. Minimum database: complete blood count, fibrinogen, and serum chemistry profile

   a. Assess hydration, acid-base status, electrolyte abnormalities, and protein status.

b. Assess renal and hepatic function.

c. Assess endotoxemia.

2. Serum protein electrophoresis and immunoglobulin quantitation

3. Serologic testing: *Ehrlichia risticii* and *Lawsonia intracellulare*

4. Peritoneal fluid analysis

III. Evaluation of feces

1. Gross appearance: severity, hemorrhage, odor, and presence of sand

2. Direct smear: evaluation of protozoan populations and presence of leukocytes and epithelial cells

3. Parasite evaluation: including evaluation for *Cryptosporidium parvum,* especially in foals

4. Evaluation of bacterial pathogens

a. Gram stain and spore stain

b. Aerobic and anaerobic culture (culture of multiple samples or rectal mucosal biopsy for *Salmonella*)

c. Clostridial toxin analysis

d. Polymerase chain reaction: *Salmonella, E. risticii,* and L. intracellulare

5. Foals: evaluation of viral pathogens, primarily rotavirus (electron microscopy and enzyme immunoassay)

IV. Diagnostic imaging: radiography and ultrasonography

V. Endoscopic examination: stomach, rectum, and descending colon

VI. Absorption tests (glucose or xylose absorption): primarily for chronic protein-losing enteropathy

VII. Histopathologic examination

VIII. Toxin evaluation: cantharidin in urine or gastrointestinal contents, arsenic in liver, or other

IX. Response to therapy

3.10.2.2

CLINICAL PATHOLOGY

Routine analysis of blood work rarely identifies a specific cause of diarrhea but can be important in directing appropriate supportive care and may help to establish whether diarrhea is caused by another condition, such as hepatic or renal disease. Some important parameters to evaluate include the presence of leukopenia, particularly neutropenia with a left shift and toxic changes in the white blood cells. These abnormalities

suggest endotoxemia, which also may be associated with thrombocytopenia and coagulopathies. One also should evaluate the concentration of protein, as well as the albumin/globulin ratio. Significant hypoproteinemia, especially hypoalbuminemia caused primarily by protein loss, may occur with acute and chronic diarrhea. Hyperglobulinemia may indicate a chronic inflammatory condition. Disturbances in acid-base balance, especially metabolic acidosis, and electrolyte abnormalities frequently occur in cases of acute diarrhea but are uncommon in chronic diarrhea. Because of the dehydration frequently seen with acute diarrhea, prerenal azotemia is common and is important to recognize because some therapies, especially nonsteroidal antiinflammatory medications, may worsen the condition. In a study of 122 horses with acute diarrhea, horses with azotemia and clinicopathologic findings consistent with hemoconcentration and hypoproteinemia were less likely to survive.[17]

The diagnostic and prognostic value of serum protein electrophoresis has been evaluated in horses with chronic diarrhea.[25] Significantly higher levels of β_1-globulin were found in horses with larval cyathostomiais than in other horses, and such values in conjunction with a decreased albumin were helpful in diagnosing intestinal parasitism. However, a normal β_1-globulin concentration was not a reliable indicator of the absence of the disease. Significantly lower albumin concentrations and significantly higher α_2-globulin concentrations were found in horses that did not survive, suggesting that these parameters are nonspecific indicators of the severity of inflammatory changes within the intestinal wall. Parasitic infections, particularly strongylosis, also may be associated with elevated serum concentrations of immunoglobulin G(T).[26]

Infrequently, immunodeficiencies are associated with diarrhea.[18,19] Therefore in some cases, further evaluation of immune status may be indicated and may include specific immunoglobulin quantitation, 159
evaluation of specific lymphocyte subsets, or functional assays. One should consider genetic testing for severe 160
combined immunodeficiency in sick foals of Arabian breeding.

Analysis of peritoneal fluid may be useful in some cases of diarrhea. Abnormalities in the peritoneal fluid may reflect the severity of inflammation and in some cases may help to establish a specific diagnosis. Increases in protein and sometimes nucleated cell count may be seen in association with ulcerative colitis.[23] In cases of bacterial peritonitis, one may find organisms on cytologic examination or culture. Occasionally, one may identify neoplastic cells in the peritoneal fluid, although their absence does not rule out the presence of neoplasia.

3.10.2.3 EVALUATION OF FECES

Evaluation of the feces may yield important information in cases of diarrhea. Even the gross appearance of the feces can be helpful. For example, profuse, watery diarrhea is not generally consistent with a diagnosis of right dorsal colitis. Frank blood in the feces suggests bleeding into the distal colon from mucosal damage. Hemorrhagic, foul-smelling feces often are seen in association with clostridial diarrhea. One also can assess the feces for the presence of occult blood, which indicates bleeding from any source. Although excess sand in the feces is readily apparent in some cases, other cases require mixing the feces in a rectal sleeve with water and allowing the sand to settle.

Microscopic examination of the feces for evidence of parasitism and evaluation of viable protozoal populations also may be useful. A direct smear of fresh feces allows for observation of the motility of ciliates and can be used as a screen for the presence of ova and oocysts, although more sensitive techniques, including fecal flotation and sedimentation, are recommended for evaluation of parasitism. Ideally, a quantitative method that allows for estimation of the number of eggs per gram of feces, such as McMaster's or Stolley's, is

recommended. However, one must remember that fecal examination for parasites sometimes can be misleading, giving false-negative results. *Cryptosporidium parvum* infection can be difficult to diagnose, but oocysts can be detected in the feces by acid-fast staining or by immunofluorescence assay.[27]

Fecal samples also can be examined microscopically for leukocytes and epithelial cells. In general the cellularity increases with the severity of diarrhea. Fecal leukocytes and epithelial cells are increased in salmonellosis, but are not specific for this disorder.[28] More than 10 leukocytes per high-power field may indicate salmonellosis.

Evaluation of the feces for infectious agents is essential in the diagnostic evaluation of horses with diarrhea. *Salmonella* and *Clostridium* species are among the most common causes of bacterial diarrhea in horses. Other less common bacterial agents include *Campylobacter* spp., *Aeromonas* spp., and particularly in weanling age 160
foals, *Lawsonia intracellulare*.[29,30] Although primarily a respiratory pathogen, *Rhodococcus equi* also can 161
cause diarrhea, particularly in foals 2 to 4 months of age.[31] *Escherichia coli* is an uncommon cause of diarrhea in foals, unlike in calves and piglets. However, enterotoxigenic strains, characterized by the presence of virulence factors, have been identified in foals. Gram stain and spore stain of fecal smears can help to identify and quantitate the bacterial populations present, particularly clostridial species. However, although large numbers of gram-positive rods or spores have been identified in foals with clostridial enterocolitis, the results of direct staining may be misleading.[32,33] In one study, *Clostridium perfringens* was cultured from 59% of samples in which no gram-positive rods were visible. Some clostridial strains also are likely part of the normal microflora.[34] Large numbers of yeast in the feces should alert the clinician to the possibility of candidiasis, especially in compromised neonatal foals.

Fecal culture is used commonly to establish a diagnosis in cases of bacterial diarrhea. When culturing feces, especially if an outside laboratory is used, one must consider proper sample handling, particularly for anaerobic clostridia.[35] *Salmonella* spp. are one of the most significant bacterial pathogens in equine feces.[36] Although the number of *Salmonella* spp. organisms isolated from the feces of horses with clinical salmonellosis is generally greater than from horses with asymptomatic infections, the volume of feces in horses with profuse diarrhea may decrease recovery. Culture of multiple fecal samples, typically five, is recommended to increase the sensitivity. Culture of a rectal mucosal biopsy or rectal scraping is an alternative to fecal cultures and may increase sensitivity, because *Salmonella* spp. are intracellular organisms. Identifying clostridial species requires anaerobic culture. However, evaluating the presence of toxin in cases of suspected clostridial diarrhea also is critical, because *Clostridium* spp., particularly *C. perfringens* type A, may be present in normal equine feces.[34] Depending on the clostridial species and the laboratory, toxin can be assessed by detecting preformed toxin in the feces, toxin being produced by the isolate in culture, or the toxin gene in the isolate.[32–35]

An increasing number of polymerase chain reaction (PCR) assays are available for detecting causative agents of equine diarrhea. In comparing a PCR with microbial culture for detection of salmonellae in equine feces and environmental samples, the PCR method was found to be more sensitive and more rapid and required submission of fewer samples.[37,38] Currently, PCR is also available for detection of *Ehrlichia risticii,* the causative agent of Potomac horse fever, in feces and peripheral blood.[39,40] Fecal PCR analysis also has been shown to be useful in documenting equine proliferative enteropathy caused by *Lawsonia intracellulare*.[30] Serologic methods, evaluating the presence of antibodies, are additional diagnostic tests used for diagnosis of *Ehrlichia* and *Lawsonia*.[30,40]

Rotaviral infection is associated with diarrhea in foals and is most common in foals from 1 to 4 weeks of age.[4,41] One generally makes a diagnosis by detecting the virus by electron microscopy or the viral antigen by enzyme immunoassay (Rotazyme, Abbot Laboratories, North Chicago, Illinois), which is generally more sensitive than direct electron microscopy.[42] Coronavirus appears to have a low prevalence in foals but has been isolated from a horse with diarrhea.[43]

Less commonly used tests include evaluation of fecal osmolality and electrolyte concentrations (sodium and potassium). If the concentration of sodium plus potassium is much less than the osmolality, the result indicates the presence of osmotically active nonelectrolytes, confirming an osmotic diarrhea.

3.10.2.4 DIAGNOSTIC IMAGING

Diagnostic imaging, although particularly useful in foals, also can be valuable in adult horses. In foals, radiographs can detect gas distention in the lumen of the gastrointestinal tract, and the gas pattern may help to differentiate ileus from mechanical obstruction. Occasionally, gas may be seen within the bowel wall in severe cases of clostridial necrotizing enterocolitis. In adult horses, abdominal radiography is limited somewhat by having the proper facilities and equipment to perform the procedure safely. However, radiographs can be effective in identifying radiodense material, such as enteroliths and sand. Ultrasonography can be used in horses of all ages to evaluate the amount and character of the peritoneal fluid, masses, intestinal distention, and wall thickness. In cases of right dorsal colitis, the diagnosis has been supported by ultrasonographic evidence of thickening of the right dorsal colon. Altough isotope-labeled white blood cell scintigraphic scans also may help identify colonic ulcerations, the availability and sensitivity of the procedure are limited.

3.10.2.5 OTHER DIAGNOSTICS

Endoscopic examination of the stomach and proximal duodenum may reveal the presence of neoplasms or ulceration. Diarrhea and inappetance are common clinical signs in symptomatic foals with ulceration of the squamous gastric mucosa. Endoscopy also can be used for inspection of the mucosa of the rectum and descending colon, allowing for evaluation of mural masses or mucosal inflammation.

Absorption tests are used primarily in cases of chronic diarrhea or weight loss to evaluate the small intestinal absorptive capacity. Oral glucose and oral xylose absorption tests have been used.[44,45] Although the plasma concentration of glucose may reflect glucose metabolism as well as absorption from the gastrointestinal tract, the assay has been shown to be reliable in the diagnosis of significant malabsorptive conditions. Xylose is influenced less by the metabolic status of the horse, but the compound is more expensive than glucose, and the assay is not available in many laboratories. Results of both assays are nonspecific, but abnormal results support malabsorption and may indicate the necessity of biopsy.

Diagnosing neoplasms and chronic inflammatory or infiltrative disorders often requires histopathologic examination. A rectal mucosal biopsy is easy to collect and also can be cultured, but the area that can be reached for biopsy is limited. Laparoscopy allows for visualization of the abdomen and certain biopsies. One can obtain full thickness intestinal biopsy during exploratory celiotomy.

Diarrhea is a component of the clinical syndrome associated with several toxins. Cantharidin (blister beetle toxin) can be detected in urine or gastrointestinal contents.[46,47] One can measure lead in the blood and liver, selenium in the blood and liver, or arsenic in the liver if they are suspected.[47,48] One should consider oleander

toxicity in horses with diarrhea, arrhythmias, and renal disease, especially if exposure is possible.[47] Oleandrin is detectable in urine and gastrointestinal contents.

3.10.2.6 EVALUATION OF RESPONSE TO THERAPY

Evaluating the response to empirical therapy may be helpful in some cases of chronic, undiagnosed diarrhea. Dietary changes may decrease diarrhea in some cases, and often a diet of grass hay alone is recommended. In cases in which right dorsal colitis is suspected but cannot be confirmed, using pelleted feed may be beneficial. Addition of psyllium mucilloid and corn oil to the diet also may be beneficial in right dorsal colitis. Psyllium mucilloid also has been used in cases in which sand was suspected as contributing to the diarrhea. Any medications that the horse has been receiving, especially nonsteroidal antiinflammatory drugs or antibiotics, should be discontinued in case they are contributing to the diarrhea.

Transfaunation can be used in an attempt to restore normal flora. Fresh colonic or cecal contents are considered the best source of organisms, but feces can be used. A number of commercial probiotics are available, but their efficacy has not yet been established.

A course of corticosteroids can be tried in cases of chronic diarrhea in which infectious causes have been ruled out. Treatment with a larvicidal anthelmintic may be beneficial in some cases, and sometimes is used with corticosteroids. Some horses with chronic diarrhea have responded to iodochlorhydroxyquin (10 g/450 kg/day for 2 weeks). This drug sometimes has been used concurrently with trimethoprim-sulfa. Occasionally, transfusion with plasma seems to suppress diarrhea in young horses. 161

3.11

3.11—Clinical Assessment of Poor Performance

Melissa T. Hines

Any decrease in performance may be critical to the equine athlete. Numerous factors influence performance, including genetics, training, desire, and overall health. Peak athletic performance requires optimal function of all body systems, particularly those involved in locomotion and oxygen transport.

3.11.1 Approach to Poor Performance

Determining the cause of poor performance in those horses without overt clinical disease often is challenging.[1–4] In a study by Martin, Reef, Parente et al. of 348 cases of poor performance, a definitive diagnosis was established in 73.5% of cases after in-depth examination, which included the use of a high-speed treadmill.[3] Subtle abnormalities may be sufficient to impair performance, and in some cases, problems may be evident only during exercise, contributing to the difficulty of making a diagnosis. Additionally, multiple problems may occur concurrently. In a study by Morris and Seeherman of 275 racehorses with a history of poor racing performance, 84% were found to have more than one abnormality.[2] Therefore determining the actual clinical significance of any given problem may be difficult.

Equine athletes presented for poor performance should undergo a comprehensive evaluation, the basic components of which include a history, detailed physical examination, and laboratory screening. The clinician should emphasize examination of the respiratory, musculoskeletal, and cardiovascular systems, because these systems most often are linked to performance problems. In many cases, standardized exercise testing, generally on a high-speed treadmill, is critical in identifying the problem. Endoscopic examination of the upper airways during exercise has proved particularly useful.

3.11.2 History

Obtaining a complete history is a fundamental part of evaluating poor performance. The clinician should establish the use of the horse, the time in training, and the specifics of the training program. Determining whether the horse has never performed as expected or has experienced a decline in the level of performance is crucial. If the horse has never performed as expected, one should consider a lack of ability, congenital abnormalities, or training problems. A change in performance, either sudden or insidious, often is associated with an acquired problem. The clinician should characterize specifically the decline in performance, including the intensity of exercise at which signs are observed and whether performance is abnormal from the onset of exercise or declines during an exercise bout. In those cases in which performance drops off during exercise, the clinician should determine whether the decline is acute or gradual and whether any other signs such as stridor are associated with it.

Other elements of the history with particular relevance to athletic performance include any previous respiratory disease, respiratory noise, or respiratory distress associated with exercise. Any change in gait also may be significant. Establishing the feeding practices, changes in appetite or body condition, the type of tack used, and whether sweating is appropriate is important. The clinician should determine the response to any medications that have been used, such as phenylbutazone or furosemide. The information obtained in the history may help direct the investigation.

3.11.3 General Physical Examination and Laboratory Screening

The clinician should perform a complete physical examination in all cases. Hematologic testing and a biochemical profile are indicated, although in most horses presented for poor performance without obvious clinical abnormalities, routine evaluation of a single sample is within normal limits. Because exercise can induce some changes in laboratory parameters, such as an increase in the packed cell volume and neutrophil count, 163
considering the time of sample collection relative to exercise is important.[5–7] Potentially significant findings 164

include changes consistent with chronic inflammation, such as anemia, hyperglobulinemia, and possibly hyperfibrinogenemia. Subclinical infections may have only slight alterations in the leukocyte count and differential. Viral infections, especially in the early stages, may be associated with a leukopenia and neutropenia. A decrease in the neutrophil-to-lymphocyte ratio has been associated with overtraining, although this is not a reliable correlation.[7]

Horses at rest normally maintain a significant proportion of red blood cells and hemoglobin in the splenic reserve.[5,6,8] Thus although total body hemoglobin increases in response to training and may correlate with performance, such cannot be determined from a resting sample. Special techniques must be used to document total red cell mass or hemoglobin.[8,9] Anemia can decrease the oxygen-carrying capacity during exercise, resulting in suboptimal performance.

Signs of organ dysfunction in horses presented for poor performance are not common findings. Muscle enzymes may be elevated, although many cases of myopathy are subclinical and require evaluation of muscle enzymes after exercise.[10] Much attention has been paid to the importance of electrolytes and exercise; however, abnormalities seldom are found. In general, circulating electrolyte concentrations are regulated tightly and may not reflect closely the total body electrolyte status.[11] However, a concentration of potassium consistently below 3 mEq/L may suggest a potassium deficit. Chronic electrolyte deficiencies may be detected by performing renal fractional excretion of electrolytes.

3.11.4 Evaluation of the Respiratory System

The clinician should give careful attention to examining the respiratory tract, because abnormalities of this system frequently influence performance. The examination should include evaluation of air flow from the nares and percussion of the sinuses, as well as assessment of any cough or nasal discharge. Careful palpation of the larynx may reveal an increase in prominence of the muscular process of the left arytenoid cartilage resulting from a loss of mass of the left dorsal cricoarytenoid muscle associated with idiopathic hemiplegia. The clinician can use the laryngeal adductor response test, or slap test, to evaluate adduction of the arytenoid cartilages by slapping the withers during expiration and evaluating movement of the contralateral arytenoid by endoscopy or palpation. The clinician should perform a thorough auscultation of the trachea and lungs. Having the horse rebreathe from a plastic bag placed over the nostrils increases the respiratory rate and tidal volume, accentuating sounds. In addition to auscultation, one should note the character and pattern of respiration, including the presence of any abdominal component, and the recovery time. Percussion of the thorax may be useful in establishing the lung border and any dull or hyperresonant areas, as well as in detecting pleural pain.

Dynamic obstruction of the airway is among the most common causes of poor performance in the equine athlete.[2,3,12–14] In the study by Morris and Seeherman of 275 racehorses evaluated for poor performance, 40% were found to have dynamic obstruction.[2] Similarly, in the study by Martin, Reef, Parente et al. of 348 racehorses and show horses with poor performance, 148 (42.6%) had dynamic obstruction of the airways.[3] Of these 148 affected horses, 39 were found to have multiple airway abnormalities. An additional 22 horses had dynamic airway obstruction concurrently with a cardiac arrhythmia. In both studies of poor performance the most common conditions causing airway obstruction were dorsal displacement of the soft palate and idiopathic left laryngeal hemiplegia with arytenoid collapse. Other conditions diagnosed included dynamic pharyngeal collapse, epiglottic entrapment, subepiglottic cyst, rostral displacement of the palatopharyngeal arch, and redundant alar folds. An important note is that many of the horses with airway obstruction did not have a history of abnormal respiratory noise and did not have abnormalities at rest. Also, not all abnormalities observed at rest caused

obstruction. Therefore these studies emphasize the importance of treadmill videoendoscopy as a component of the evaluation of poor performance. In most cases, the clinician should perform a treadmill videoendoscopy regardless of the history and physical examination findings.

Endoscopy also can be useful in identifying respiratory problems other than dynamic airway collapse. For example, one can identify narrowing of the ventral nasal meatus associated with sinusitis, nasal masses, and pharyngitis. If the endoscope is sufficiently long, tracheal injury and secretions in the lower respiratory tract can be visualized. Sampling of airway secretions by bronchoalveolar lavage may aid in the diagnosis of low-grade respiratory infections, small airway inflammatory disease, or exercise-induced pulmonary hemorrhage. In some cases, evidence of inflammation and retropharyngeal lymphadenopathy on endoscopic examination of the guttural pouches has been associated with dorsal displacement of the soft palate, which may result from 164
neuropathy of the pharyngeal branch of the vagus nerve.[15] 165

Radiographs and ultrasound may be indicated on evaluation of the respiratory system of horses with poor performance, especially in those horses with evidence of lower respiratory tract disease. Radiographs also can be useful in assessing upper respiratory disorders, allowing for the evaluation of soft tissue masses or fluid accumulations. In addition, sometimes one can identify abnormalities of the pharyngeal and laryngeal structures such as thickening of the soft palate or hypoplasia of the epiglottis.

3.11.5 Evaluation of the Cardiovascular System

Any decrease in cardiac output potentially can limit performance, making thorough evaluation of the cardiovascular system essential. On basic physical examination, the clinician should evalutate the mucous membrane color, capillary refill time, and arterial and venous peripheral pulses, although finding abnormalities in these parameters in horses presented for decreased performance is uncommon. One should perform careful auscultation of the heart on both sides of the thorax to evaluate the cardiac rhythm and murmurs. Many horses have murmurs that are of little clinical significance.[2,16] In the study by Martin, Reef, Parente et al., 102 of the 348 horses were found to have murmurs, the most common being mitral regurgitation.[3] In all cases the murmur was determined to be clinically unimportant.

The clinician can use electrocardiography to evaluate the cardiac rhythm further, and ideally should perform the procedure before, during, and after exercise using radiotelemetry. Cardiac arrhythmias were the only abnormality found in 33 of the 348 horses evaluated by Martin, Reef, Parente et al. and were found in conjunction with dynamic airway obstruction in 22 horses.[3] However, in the study by Morris and Seeherman, arrhythmias were noted in just 2 of 275 horses.[2] The most frequent arrhythmias observed include atrial and ventricular premature depolarizations. Ventricular tachycardia and paroxysmal atrial fibrillation also have been noted. Changes in the T wave, once thought to be related to poor performance, and second-degree atrioventricular block have been found to have no effect on exercise capacity.[17]

Echocardiography before and after exercise helps to evaluate cardiac function. Martin, Reef, Parente et al. found decreased fractional shortening indicating left ventricular dysfunction after exercise in 19 horses, only 8 of which had echocardiographic changes at rest.[3] Six of the 19 horses had clinically significant arrhythmias. Myocardial disease may contribute to left ventricular dysfunction and arrhythmias. Elevations in myocardial fractions of creatine kinase, lactate dehydrogenase, and troponin support myocardial disease but are not present in all cases.

3.11.6 Evaluation of the Musculoskeletal System

A surprising number of horses presented for poor performance are found to be lame, even when lameness is not part of the presenting complaint.[1,2,4] Therefore the clinician should perform a complete lameness examination in all cases. In some horses presented for poor performance, the gait asymmetry may be subtle and only discernable at high speed, making diagnosis by traditional methods difficult. In these cases, gait analysis on the treadmill and advanced diagnostic techniques such as nuclear scintigraphy, thermography, and computed tomography or magnetic resonance imaging may be useful. One also should perform a neurologic examination to identify any deficits that could contribute to poor performance.

Myopathy can lead to decreased performance. In many cases the condition is subclinical and requires an exercise challenge test to make the diagnosis.[3,10] One should measure creatine kinase before exercise and ideally 4 to 6 hours after an exercise bout consisting of 15 to 30 minutes at the trot. In normal horses, this light exercise rarely causes more than a threefold increase in creatine kinase. An increase of fivefold or more indicates exertional rhabdomyolysis. A muscle biopsy can help to define the myopathy. In the study by Martin, Reef, Parente et al., 10 of 348 horses developed clinical exertional rhabdomyolysis after exercise, and an additional 53 demonstrated subclinical myopathy as demonstrated by increased creatine kinase levels after exercise.[3]

3.11.7 Exercise Testing

Exercise testing provides a mechanism for evaluating a range of body systems under standard exercise conditions. In particular, measurements of cardiorespiratory and metabolic function taken during an exercise test provide information about the capacity and efficiency of key body systems involved in energy production. From a clinical standpoint, exercise testing is generally most useful in assessing the effect on performance of abnormalities found on a physical examination. Testing also may help to establish the reason for reduced athletic capacity in horses that have no abnormalities on basic examinations. Exercise testing can be done in the field, which mimics the condition in which the horse actually performs. However, most testing is currently done on a treadmill, which provides more standard conditions and an opportunity to perform a greater range of measurements. The specific protocol used for exercise testing may vary somewhat.[1,18,19] Occasionally a high-speed test is performed in which the horse is accelerated rapidly to maximum speed and run to fatigue. However, the most common type of test is an incremental test in which the speed increases every 1 to 2 minutes until the horse reaches fatigue, allowing for the generation of data during submaximal and maximal exercise. In most cases the test is performed with the treadmill at a slope of 10%. This slope is not so steep as to be completely 165
unrepresentative of normal exercise, and yet it ensures that maximum intensity exercise can be performed 166
without reaching speeds that may be too fast for horse safety. Some parameters that can be assessed in an exercise test include heart rate, blood lactate level, arterial blood gases, total red cell volume, stride length, and oxygen uptake. As previously discussed, treadmill videoendoscopy is often valuable.

3.11.7.1 HEART RATE DURING EXERCISE

Evaluation of the heart rate during exercise provides an indirect index of cardiovascular capacity and function. Several heart rate monitors are available.[20] Radiotelemetry also can be used to evaluate the heart rate and rhythm, particularly at the end of exercise. Because the stroke volume does not change greatly with increasing exercise speed, the heart rate provides a guide to changes in cardiac output. In general, a linear increase in heart rate occurs with increasing exercise speed up to the point at which the maximal heart rate is reached.[21–]

[23] The maximal heart rate (HRmax) is identified when no further increase in heart rate occurs despite an increase in exercise speed. The HRmax does not change with training state, although the speed at which it is reached increases with increasing fitness.

One reference point for comparison of cardiovascular capacity is the treadmill speed at a heart rate of 200 bpm (V_{200}). At a heart rate of 200 bpm, most horses are close to the point of onset of blood lactate accumulation. The V_{200} can be calculated by linear regression analysis or plotted using measurements taken at three to four submaximal exercise speeds, without the horse reaching maximal exercise. One should take care when using the V_{200} to assess exercise capacity, because at a heart rate of 200, horses may be exercising at different proportions of their HRmax and therefore their maximal oxygen uptake (VO_{2max}). In general, however, horses with the highest cardiovascular and metabolic capacities have the highest V_{200} values; that is, the better horses reach a heart rate of 200 at higher speeds than those with a lower exercise capacity. The V_{200} increases with training and can be useful for monitoring changes in fitness. The better quality Thoroughbreds have a V_{200} of 8 to 9 m/sec in an exercise test with the treadmill set at a 10% slope. Values less than 7 m/sec are abnormal and if found in a fit horse indicate decreased cardiac capacity.

Another measurement of cardiovascular capacity is the treadmill speed at which the horse reaches HRmax, known as V_{HRmax}. This value correlates with VO_{2max} and exercise capacity but requires the horse to exercise up to maximal speeds so that a plateau in heart rate can be identified.

Heart rate measurements are helpful in determining the actual significance of cardiac abnormalities such as murmurs and arrhythmias. In horses with functional cardiac disease the reduced stroke volume necessitates higher heart rates to maintain adequate cardiac output. Also, studies in Standardbred racehorses have suggested that horses with musculoskeletal problems have an increased V_{200} and that monitoring the V_{200} may help to identify subclinical lameness.

3.11.7.2 BLOOD OR PLASMA LACTATE MEASUREMENT

Exercising muscles produce lactate to some extent during all intensities of exercise, but production increases exponentially with the intensity of exercise.[23–25] As exercise becomes more intense, the aerobic energy contribution becomes insufficient to meet total energy requirements, and increased anaerobic metabolism results in increased lactate production. Lactate diffuses from muscle to blood, and therefore blood or plasma concentrations of lactate reflect muscle lactate. Some evidence suggests that whole blood concentrations most accurately measure lactate accumulation, because red blood cells actively take up lactate.[25–28]

The rate of increase of lactate in the blood may be used as an indirect indicator of cardiovascular and metabolic capacity. Horses with the highest aerobic capacities because of a high maximal cardiac output tend to have lower lactate values at submaximal exercise intensities than those with lower aerobic capacities. Lactate values can be used to compare horses or to evaluate training in the same horse. The treadmill speed at which a plasma lactate of 4 mmol/L (V_{LA4}) is reached is one measure of lactate production, and a high value reflects good aerobic capacity. The V_{LA4} has been used to monitor changes in fitness. In fit Thoroughbred horses 3 years of age and over, values for V_{LA4} range from 8.0 to 9.5 m/sec. Horses that are not fit or have respiratory disease have lower values. Another useful reference is the blood or plasma lactate at conclusion of the 10 m/sec exercise step of the incremental test, and highly fit, athletic horses usually have values less than 5 mmol/L. High-quality sprint horses, which perform largely under anaerobic conditions and have a high anaerobic capacity, may have high peak lactate values.

3.11.7.3 OXYGEN UPTAKE

The measurement of oxygen uptake (VO_2) is critical to assessing athletic performance.[21,22] The VO_{2max} has been used as a key indicator of exercise capacity in human athletes since the 1950s. As the VO_2 increases linearly with increasing treadmill speed, VO_{2max} can be identified when VO_2 reaches a plateau despite an increase in speed. The Thoroughbred horse has VO_{2max} values that are higher than those of many other mammalian species when expressed on a mass-specific basis. The major factor responsible for the high 166
VO_{2max} in athletic horses is their high oxygen-carrying capacity, which arises from a high maximum stroke 167
volume and to some extent a large arteriovenous oxygen content difference. The VO_{2max} is a good index of changes in fitness and a measurement of exercise capacity in performance horses.

3.11.7.4 MAXIMUM OXYGEN PULSE

The oxygen pulse is defined as the VO_2/heart rate and is expressed as ml/kg/beat. This value provides an indication of the maximum stroke volume, and in high-quality horses, values range from 0.66 to 0.76 ml/kg/beat. Those horses with cardiac problems resulting in low cardiac outputs and individuals with low VO_{2max} values usually have values in the range of 0.5 to 0.56 ml/kg/beat. The maximum oxygen pulse also has been shown to correlate with treadmill total run time.

3.11.7.5 ARTERIAL BLOOD GAS ANALYSIS DURING EXERCISE

Arterial blood gas analysis during exercise may be indicated, especially in horses in which respiratory disorders are the suspected cause of poor performance. For an accurate blood gas analysis, one should take into account the temperature of the blood because it may reach 42° C during maximal exercise. At exercise intensities above 65% VO_{2max}, athletic horses become hypoxemic, although the extent varies between individuals.[29–32] Horses with low VO_{2max} values do not necessarily have a significant decrease in arterial oxygen tension.

3.11.7.6 HEMATOCRIT AND TOTAL RED CELL VOLUME DURING EXERCISE

The total volume of red cells is a major determinant of oxygen-carrying capacity, and therefore measurement of red cell volume can give some index of exercise capacity. A postexercise packed cell volume test is not a reliable indicator of total red cell volume primarily because of plasma volume variations, but it does provide a rough estimate of total circulating red cells.

One can make an accurate determination of red cell volume by techniques that use dye dilution following mobilization of the splenic erythrocyte pool to measure the plasma volume. Although total red cell volume increases with training, some evidence indicates that Standardbred racehorses with overtraining syndrome may develop an abnormal red cell hypervolemia that contributes to poor performance.[9]

3.11.7.7 PEAK RUNNING SPEED AND TOTAL RUN TIME

The peak treadmill running speed and the total run time may indicate exercise capacity. In some studies of human athletes, the peak treadmill running speed during an exercise test was shown to be a predictor of performance. Athletic Thoroughbred racehorses can complete 60 seconds at 13 m/sec during an incremental exercise test at a 10% slope.

3.11.7.8 STRIDE LENGTH

Athletic horses are thought to have better stride characteristics.[4,33] Some studies have shown a correlation between maximum stride length and the treadmill run time. An accelerometric device has been used to provide quantitative information about locomotory variables that may be useful in evaluating performance.[33]

4 # CHAPTER 4 PHARMACOLOGIC PRINCIPLES

Patricia M. Dowling

4.1 ## 4.1—Introduction to Clinical Pharmacology

Patricia M. Dowling

Drug administration is a daily income-generating activity in veterinary practice. Before administering a drug, the veterinarian must select a safe and efficacious dosage regimen based on the physiology of the animal and the nature and formulation of the drug. If the ultimate goal of drug therapy is to improve or cure the condition of the animal, then the veterinarian is responsible for ensuring that the selected drug will be efficacious with minimal toxicity or adverse reactions in the patient and will not result in violative residual drug residues in the tissues of food animals. Individual animals of various ages and species may vary widely in their handling of an administered drug. Given that most veterinary practitioners deal with a number of different animal species and frequently administer more than one drug at time, the great potential for error in therapy and adverse drug interactions is obvious. A basic understanding of pharmacokinetics and the effects of pathophysiology on drug disposition enables the clinician to choose optimal therapy.

4.1.1 ### Pharmacokinetics

Pharmacokinetics is the mathematics of drug dosage determination and involves mathematic evaluation of the rates of drug absorption, distribution throughout the body, metabolism, and ultimate excretion from the body. Researchers usually perform basic pharmacokinetic studies in healthy animals. Unfortunately, veterinarians often do not administer drugs to normal, healthy animals. Dosage regimens derived from studies in healthy animals may not be accurate for diseased animals. Clinical pharmacokinetics is the study of the effects of disease states or other variables (age, sex, and pregnancy) on the pharmacokinetics of drugs in animals. Clinical pharmacokinetics guides veterinarians appropriately to adjust dosage regimens determined in healthy animals to optimize treatment of diseased animals.

4.1.2 ### Plasma Drug Concentrations as Therapeutic Guidelines

Most pharmacokinetic information is derived from plasma drug concentrations, even though pharmacologic action depends on drug concentration at a particular effector site, which is often a specific drug receptor. In reality, measurement of drug concentration at the receptor site is not practical. Instead, plasma (or serum) drug concentrations are measured and assumed to represent drug concentrations in target tissues. Tissue fluids or plasma perfuse most cells in the body, and drug concentrations usually reach equilibrium between tissue fluids and the blood. For most drugs, the pharmacologic action correlates well with the drug concentration in the blood. Therefore measured plasma drug concentration is assumed to represent drug concentration at the receptor sites in the tissues.

169

170

4.1.3 ### Variation Between Drug Dose and Plasma Drug Concentration

Drug dosages needed for a therapeutic effect differ widely among individuals. The usual dose has no effect in some individuals, causes serious toxicity in others, and produces an optimal effect in a few. Several factors affect the relationship between the dosage of a drug and its concentration in plasma: its bioavailability, the body size

and fluid composition of the animal, variability in drug distribution within the body, and variability in rates of metabolism and excretion. Genetic differences in metabolism and excretion, environmental factors, disease alterations of system function and concurrent administration of other drugs affect these factors. Therefore plasma concentration of drug is not a perfect index of pharmacologic response. However, pharmacologic response relates more closely to plasma drug concentration than to drug dose. The veterinarian should never make therapeutic decisions based on the plasma drug concentration alone. One always should use knowledge of plasma drug concentration with careful medical observation and judgment.

4.1.4 Definitions in Pharmacokinetics

Pharmacokinetic information aids in determining drug dosage regimens in clinical patients. To understand how one derives drug dosage regimens and adjusts for different disease states, one necessarily must understand some basic pharmacokinetic terms. Mathematic *models* provide equations to describe drug concentration as a function of time. With an *open model*, the drug is eliminated from the body. An open model describes the fate of most drugs. With a *closed model*, the drug is recirculated within the body, as with a drug that undergoes enterohepatic recirculation. In pharmacokinetic models, a series of *compartments* that communicate reversibly with each other represent the body. A *compartment* is a tissue or group of tissues with similar blood flow and drug affinity. The drug is assumed to be distributed uniformly within a compartment. Drugs move dynamically in and out of compartments. Rate constants represent the entry and exit of drugs from each compartment. The *central compartment* is the highly perfused tissues that equilibrate rapidly with the drug. Overall drug elimination occurs only from the central compartment, because the kidneys and liver are well perfused tissues. The *peripheral compartment* is the less perfused tissues such as muscle and connective tissues. The *deep compartment* consists of slowly perfused tissues or depot tissues such as fat and bone. The presence of a deep compartment for drug distribution is important for toxins and drug residues. Most drugs in clinical use are described by one or two compartment models. Models with more than three compartments are not physiologically relevant. Describing drug disposition with compartment models creates differential equations to describe drug concentration changes in each compartment and provides a visual representation of the rate processes between compartments.

4.1.5 Rates and Orders of Reactions

The drug absorption or elimination rate is the speed with which the specified process occurs. If the amount of drug in the body (C) decreases over time (t), then the elimination rate is expressed as follows:

$$-\Delta C/\Delta t$$

The absorption and elimination rate of a drug is determined experimentally by measuring the drug concentration in the body at given time intervals. *Rate constants* relate the observed rate of a kinetic process to the drug concentration that controls the process. The elimination rate constant (K) is equal to the rate of drug elimination divided by the amount of drug in the body. The absorption rate constant (Ka) describes the rate of drug absorption into the central compartment. *Reaction order* refers to the way that drug concentration influences reaction rate.

With a *zero order* reaction the amount of drug changes at a constant time interval, regardless of the drug concentration. The rate of drug elimination is as follows:

$$\Delta C/\Delta t = -K_0$$

where K_0 is the zero order rate constant in milligrams per milliliter minute. A graph of drug concentration versus time on regular graph paper for a zero order reaction produces a straight line (Figure 4.1-1), described by the following equation:

$$C = -K_0 t + C_0$$

170

171

where C is the drug concentration at any time (t) and C_0 is the drug concentration at time zero. For most drugs, zero order elimination only occurs when elimination mechanisms become saturated (Figure 4.1-2). Renal tubular secretion and bile secretion of drugs are potentially saturable processes. The most well-known zero order reaction is the oxidation of ethanol in human beings. Ethanol has a low molecular weight (46 d) relative to most drugs (>300 d). The alcohol dehydrogenase system becomes saturated with small amounts of ethanol. To achieve mild intoxication (1 mg/ml) throughout a 75-kg person requires an intake of about 56 ml of absolute alcohol (or 4 oz of whiskey, vodka, or gin). The maximum amount of alcohol that can be eliminated is 10 ml/hr, therefore totally eliminating the original 56 ml takes 5 hours. Therefore to maintain a constant level of mild intoxication requires only 10 ml of ethanol or 25 ml of liquor per hour.

Figure 4.1-1 Drug concentration versus time for a zero order reaction produces a straight line.

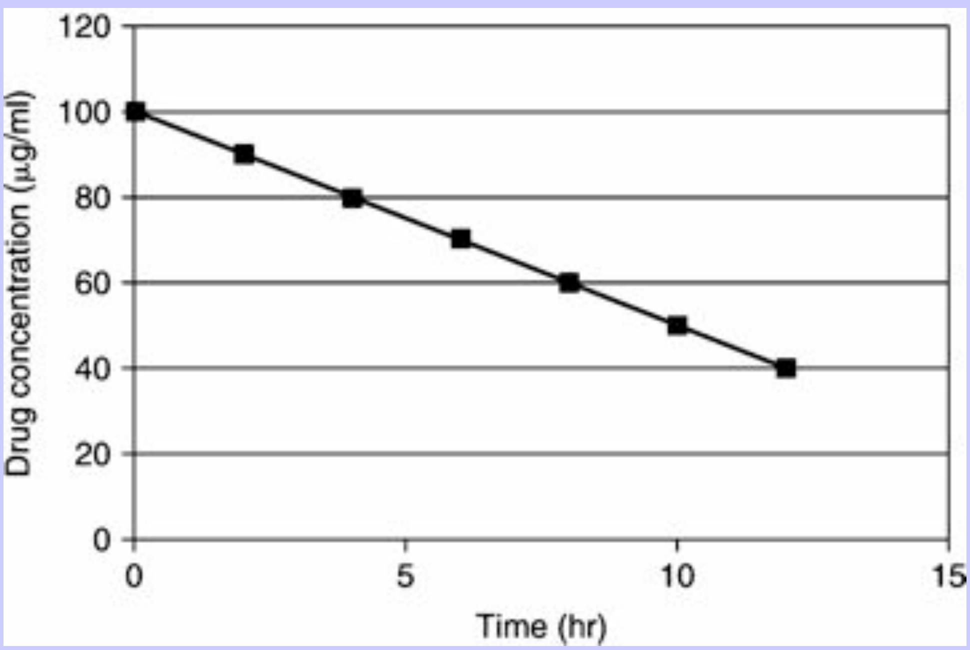

Figure 4.1-2 The effect of drug dose on drug metabolism.

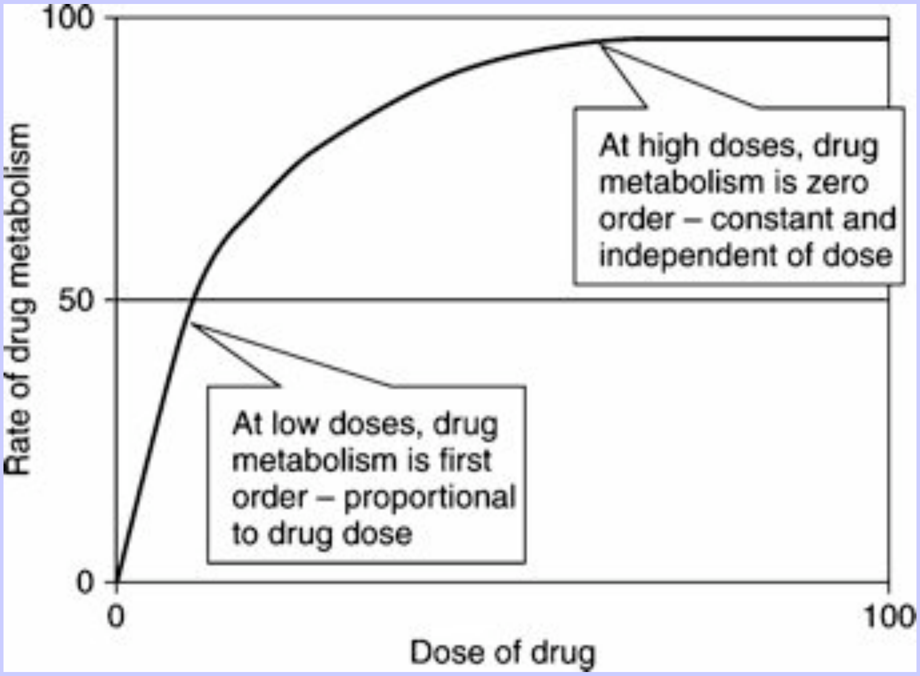


With a *first order* reaction the amount of drug changes at a rate proportional to the amount of drug remaining. The first order elimination rate is expressed as follows:

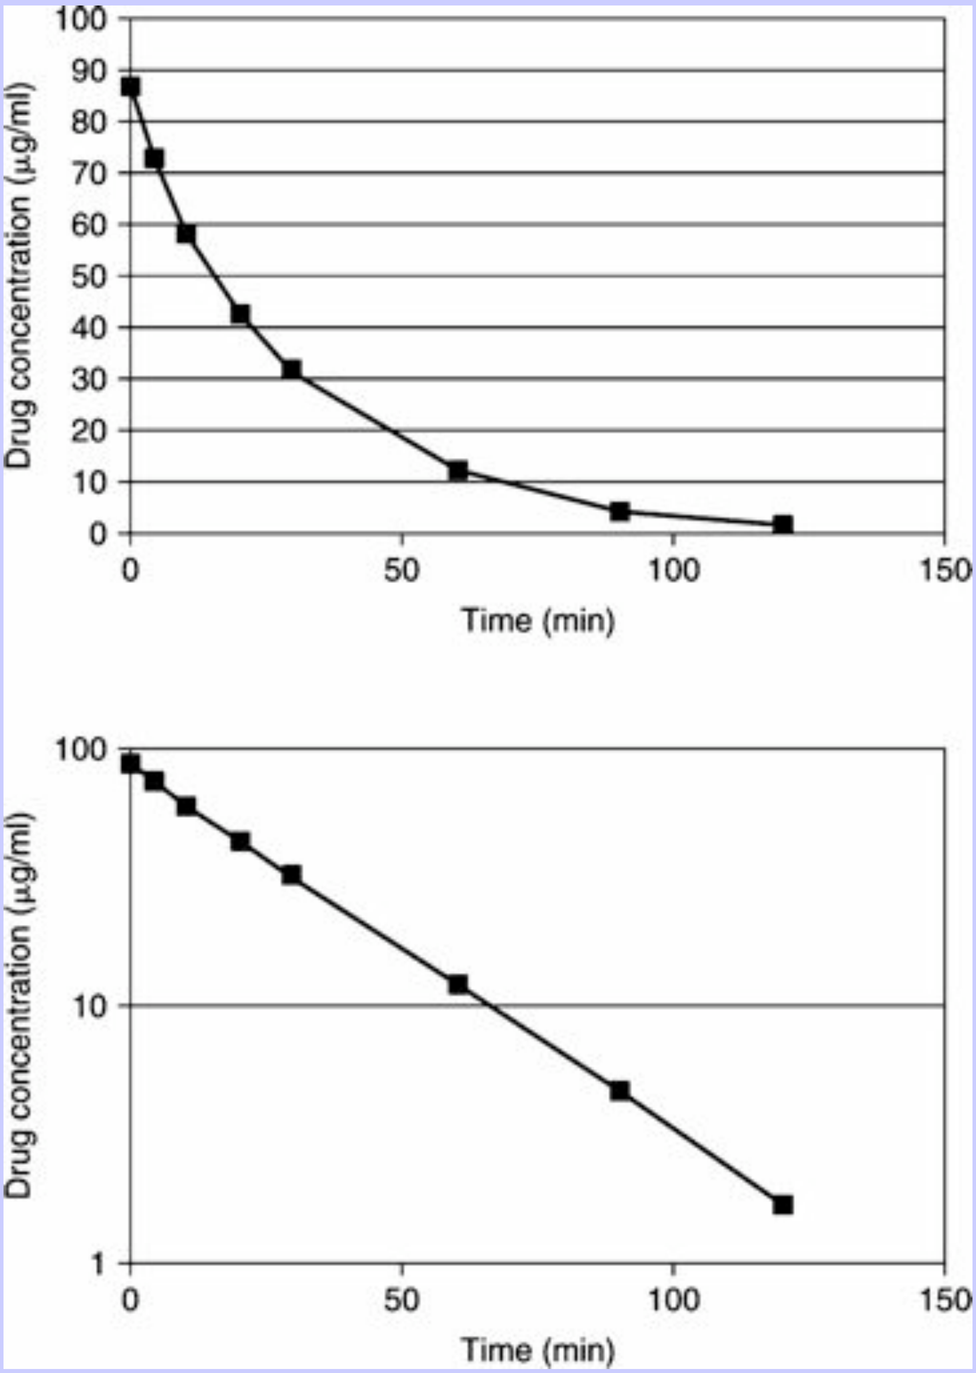
$$\Delta C/\Delta t = -KC$$

where K is the first order rate constant expressed in units of time^{-1} (minute^{-1} or hour^{-1}). K defines the fraction of drug eliminated from the body per unit time. C is the plasma drug concentration at any time (t). Although K remains constant, the rate ($\Delta C/\Delta t$) always changes, because C always decreases. A graph of drug concentration versus time for a first order reaction produces an exponential curve on regular graph paper but produces a straight line on semilogarithmic graph paper (Figure 4.1-3), as described by the following equation:

$$C = C_0e^{-Kt}$$

where C is drug concentration at any time (t), K is the first order rate constant in minutes or hours, and C_0 is the drug concentration at time zero (the moment of injection). Most drugs are absorbed and eliminated by first order processes. Glomerular filtration by the kidney is a first order process.

Figure 4.1-3 Drug concentration versus time for a first order reaction produces an exponential curve on regular graph paper but produces a straight line on semilogarithmic graph paper.



4.1.6 Clinical Application of Compartmental Modeling and Rates and Orders of Reactions

The aforementioned concepts can be combined to describe mathematically the changes in the drug concentration in the body over time. Drug disposition described by a one-compartment open model with intravenous injection and first order elimination (Figure 4.1-4) means that the body acts as one homogeneous compartment. The concentration of a drug in one part of the body is assumed to be proportional to its concentration in any other 171
part. A one-compartment open model with first order absorption and elimination describes many drugs 172
administered by routes other than intravenous, such as oral, subcutaneous, intramuscular, or intradermal (Figure 4.1-5). With a two-compartment open model with intravenous injection and first order elimination, the model assumes the body acts as two compartments: the central compartment (blood and highly vascularized tissues) and a peripheral compartment (less vascularized tissues). This model describes most drugs administered in veterinary medicine. Elimination is considered to occur only from the central compartment because the liver and kidneys are highly vascularized tissues. The plasma concentration versus time graph does not produce a straight line on semilogarithmic paper (Figure 4.1-6) but can be broken into two sections and described by the following biexponential equation:

$$C = Ae^{-\alpha t} + Be^{-\beta t}$$

where C is the concentration at any time (t), A is the y-intercept of the first portion of the curve extrapolated to zero and α is the slope of the line, whereas B is the y-intercept of the latter portion of the curve extrapolated to zero and β is its slope. The rate constants K_{12} and K_{21} describe movement of drug between the central and peripheral compartments.

Figure 4.1-4 Graphic representation of a one-compartment open model with intravenous administration and first order elimination.

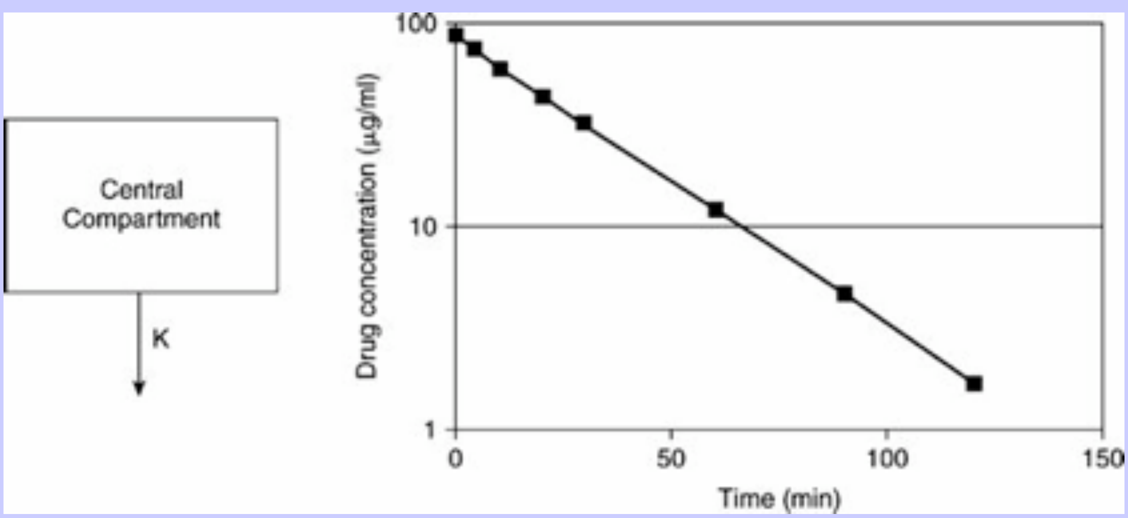


Figure 4.1-5 Plasma concentration versus time graph after intramuscular administration of long-acting oxytetracycline product to a horse, demonstrating a one-compartment open model with first order absorption and elimination.

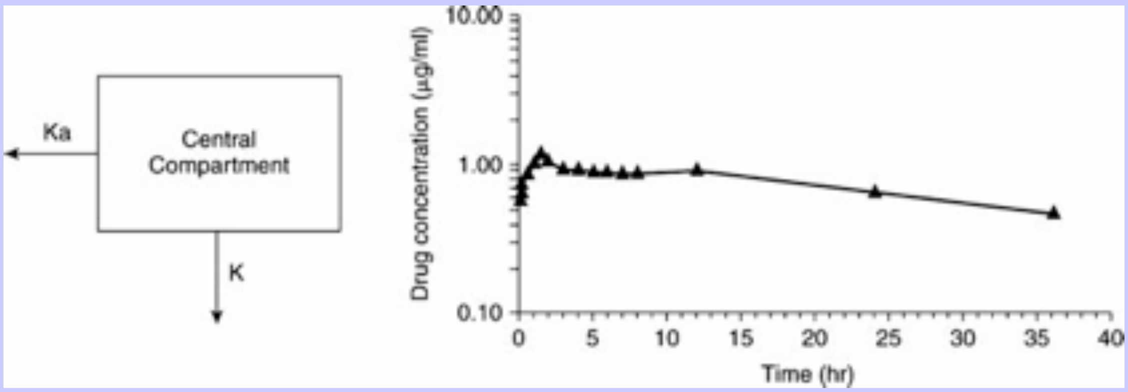
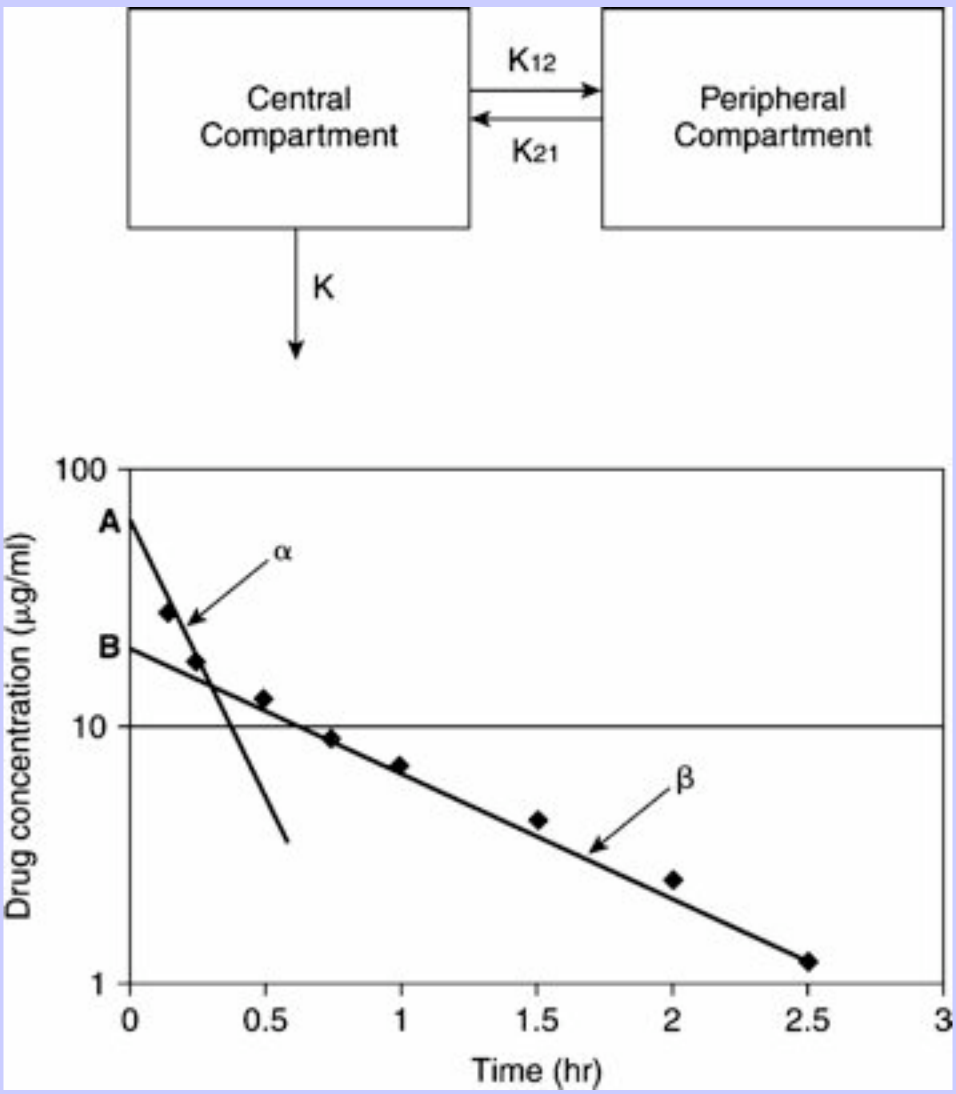


For some concentration versus time data the line can be broken into three or more straight lines and can be described mathematically with three or more exponential terms. Theoretically, drug distribution in the body can be described by as many compartments as are different tissues, but for all practical purposes, models of more than three compartments are not necessary. Drugs that are described by three-compartment models usually have some tissue site where the drug is sequestered and slowly eliminated from the body, such as the aminoglycosides, which sequester in the renal tubular epithelial cells.

4.1.7 Distribution of Drugs in the Body

The *volume of distribution* (Vd) of a drug is the mathematic term used to describe the apparent volume of the 172
body in which a drug is dissolved. The numerical value of Vd indicates the distribution of the drug in the body. 173
The ability of the drug to cross biologic membranes and reach tissues outside the vascular system determines drug distribution. The physical characteristics of the drug molecule such as ionization, lipid solubility, molecular size, and degree of protein binding determine the ability of the drug to cross biologic membranes.

Figure 4.1-6 A two-compartment open model with intravenous injection and first order elimination assumes the body acts as two compartments: the central compartment (blood and highly vascularized tissues) and a peripheral compartment (less vascularized tissues). The plasma concentration versus time graph does not produce a straight line on semilogarithmic paper but can be broken into two sections and described by a biexponential equation.



The value of Vd relates to the dose of drug administered and the amount of drug measured in a blood sample by the following equation:

$$Vd = Dose/C_0$$

where C_0 is the concentration at time zero, extrapolated from the plasma concentration versus time graph. A drug administered intravenously rapidly distributes in the extracellular fluid (ECF). A drug that does not cross lipid membranes readily will be confined mainly to the ECF. A plasma sample therefore will have a high drug concentration. The higher the measured concentration in relation to the original dose, the lower the numerical value for Vd. Drugs such as the β-lactam and aminoglycoside antibiotics are poorly lipid soluble and so remain predominantly in the ECF and have low values for Vd.

Some drugs readily cross lipid membranes and distribute into tissues. A plasma sample will have a low drug concentration in proportion to the original dose and therefore will have a high numerical value for Vd. Given the limitations in measuring drug concentrations at time zero and using the formula given previously, highly lipid soluble drugs can have measured plasma drug concentrations low enough to result in a value of Vd that is greater than 1 L/kg. Comparing the Vd of a drug to the distribution of water in the body to get an idea of the distribution of the drug is useful. Drugs with a Vd value of less than 0.3 L/kg are confined predominantly to the ECF, whereas drugs with a Vd value greater than 1 L/kg are highly lipid soluble (Box 4.1-1). In general, the higher the value of Vd, the more likely the drug molecules will reach sequestered sites such as the brain and cerebrospinal fluid, the prostate and other sex organs, the eye and the mammary gland. Although the value of Vd is useful to predict the extent of distribution of a drug, it does not confirm penetration of a drug to specific tissues. In the pharmacokinetic literature, several different terms for Vd occur, such as volume of distribution at steady state or volume of distribution by area. These values differ slightly, but they all indicate the ability of the drug to cross membrane barriers and can be considered interchangeable.

4.1.7.1 BOX 4.1-1 VOLUME OF DISTRIBUTION (Vd) OF VARIOUS DRUGS

4.1.7.1.1 Low Vd Drugs (<0.3 L/kg)

Aminoglycosides

β-Lactams

Nonsteroidal antiinflammatory drugs

4.1.7.1.2 Medium Vd Drugs (0.3-1 L/kg)

Florfenicol

Phenobarbital

Sulfonamides

4.1.7.1.3 High Vd Drugs (>1 L/kg)

Chloramphenicol

Fluoroquinolones

Macrolides

Metronidazole

Rifampin

Tetracyclines

Trimethoprim

173

174

4.1.7.2 CONDITIONS THAT AFFECT VOLUME OF DISTRIBUTION

The Vd is constant for any drug and only changes with physiologic or pathologic conditions that change the distribution of the drug. Clinically, any condition that changes ECF volume dramatically affects the plasma concentrations of drugs with low Vd values. Changes in body water status typically do not affect drugs with high Vd values significantly. Many medical conditions affect the distribution of a low-Vd drug in a patient. Neonates have a higher percentage of body water than an adult animal (80% versus 60% total body water). The extra 20% is confined primarily to the ECF. Many conditions in horses are characterized by volume contraction and dehydration, which primarily affect the ECF. Changes in acid-base balance and alterations in protein binding also can affect the Vd of a drug.

4.1.7.3 BIOAVAILABILITY

Bioavailability (F) is a measure of the systemic availability of a drug administered by a route other than intravenous. One determines bioavailability by comparing the area under the plasma drug concentration curve versus time (AUC, area under the curve) for the extravascular formulation to the AUC for the intravenous formulation. AUC is calculated by computer or by the *trapezoidal method* in which the entire curve is divided into trapezoids and the area of each trapezoid is calculated and summed to give the AUC. For an orally administered drug, bioavailability is calculated as follows:

$$F = (AUC_{oral}/AUC_{iv}) \times 100 = \%\ \text{Bioavailable}$$

If F is significantly less than 100%, the drug dose must be increased to achieve systemic drug concentrations similar to the following intravenous formulation:

$$\text{Adjusted dose} = \text{Dose}_{iv}/F$$

If the oral formulation of a drug has a bioavailability of 50%, one must double the drug dose to achieve the same concentrations in plasma as achieved using the intravenous formulation. Poor oral bioavailability is a major limitation of many drugs administered to horses. If the bioavailability is low, the oral route of administration may not be feasible.

4.1.7.4 LIPID SOLUBILITY AND DRUG IONIZATION (THE pH-PARTITION HYPOTHESIS)

The degree of lipid solubility determines how readily a drug crosses biologic membranes. Drugs are classified as lipid soluble (or nonpolar) versus water soluble (or polar). Highly lipophilic drugs diffuse easily across almost all tissue membranes. Most of the drugs used in equine practice exist as weak acids or weak bases. Their lipid solubility depends greatly on their degree of ionization (charged state). An *ionized* drug is hydrophilic and poorly lipid soluble. A *nonionized* drug is lipophilic and can cross biologic membranes. The

degree of ionization for a weak acid or weak base depends on the pK_{α} of the drug and the *pH* of the surrounding fluid and is calculated from the *Henderson-Hasselbach* equations.

For a weak acid the equation is as follows:

$$pH = pK_a + Log(ionized\ drug/nonionized\ drug)$$

For a weak base the equation is as follows:

$$pH = pK_a + Log(nonionized\ drug/ionized\ drug)$$

When the pH is equal to the pK_a of the drug, then the drug is 50% ionized and 50% nonionized (log 1 = 0).

Although one can calculate the precise proportions of ionized versus nonionized drug from the Henderson-Hasselbach equations, one can understand the relevance of the equations simply by remembering *"like is nonionized in like."* For example, a weak acid is most nonionized in an acidic environment, so aspirin is most nonionized in the stomach and is absorbed readily. The fluid of most sequestered sites in the body (cerebrospinal fluid, accessory sex gland fluid, milk, and abscesses) has a pH more acidic than plasma. In cattle with mastitis, weak acid antibiotics are administered by intramammary infusion, whereas weak bases are administered parenterally. This makes sense from the pH-partition concept. Milk is more acidic than plasma. Weak bases in the plasma are highly nonionized and readily cross into the mammary gland, and then as the equilibrium shifts, they become ion-trapped in the more acidic milk. The fraction of nonionized drug in the mammary gland is available to cross the bacterial membrane for antimicrobial action. Weak acids are highly ionized in plasma and therefore do not penetrate into the mammary gland well and so typically are administered by local infusion.

Typically, drugs that are weak acids have low Vd values, whereas weak bases have high Vd values (Box 4.1-2). Amphoteric drugs such as the fluoroquinolones and tetracyclines have acidic and basic groups on their chemical structures. These drugs have a pH range in which they are maximally nonionized. For example, enrofloxacin is most lipid soluble (nonionized) in the pH range of 6 to 8 and so is lipid soluble at most physiologic pHs. In acidic urine, significant ionization occurs that reduces enrofloxacin antibacterial activity, but this reduction in activity is offset by the high concentration of enrofloxacin achieved in urine and so is of no clinical importance. Despite being weak bases, the aminoglycosides are large, hydrophilic molecules and are highly ionized at physiologic pHs. Therefore, parenterally administered aminoglycosides do not achieve therapeutic concentrations in milk, accessory sex gland fluids, abscesses, or cerebrospinal fluid. 174

175

Amphoteric Drugs

Fluoroquinolones

Tetracyclines

4.1.7.5

DRUG-PROTEIN BINDING

Many drugs in circulation are bound to plasma proteins, mainly albumin and acute phase proteins. Bound drug is too large to pass through biologic membranes, so only free drug is available for delivery to the tissues and to produce the desired pharmacologic action. Equilibrium exists between free and bound drug, however, just as in the relationship of ionized and nonionized drug. The degree of protein binding is only clinically significant with those drugs that are more than 90% protein bound (Box 4.1-3). For these drugs, any condition that changes the amount of bound drug causes significant increases in the amount of free drug available for pharmacologic action. In addition, increasing the concentration of free drug also transiently increases the elimination of the drug as more drug enters the organs of elimination (liver and kidney), so the absolute increase in drug available for pharmacologic (or toxic) effect is somewhat lessened but still may cause clinical problems. Some of the conditions characterized by alterations in plasma proteins include hepatic insufficiency, renal failure, protein-losing enteropathies, parasitism, and burns.

4.1.7.5.1

BOX 4.1-3 EXAMPLES OF HIGHLY PROTEIN-BOUND DRUGS (>90%)

Aspirin

Ceftiofur

Diazepam

Flunixin meglumine

Furosemide

Phenylbutazone

Propranolol

Quinidine

Warfarin

Many drug interactions occur as a consequence of protein binding. If when a second highly protein-bound drug is administered, it uses the same binding site as the first drug, it can displace the first drug and increase the amount of the first drug available for pharmacologic action. The phenylbutazone-warfarin interaction is well known[1]; however, no adverse effects occur from administering aspirin and ceftiofur concurrently, because they bind to different sites.[2]

4.1.8 Drug Elimination From the Body

Drug elimination refers to the irreversible removal of drug from the body by all routes of elimination. Elimination may be divided into two major components: excretion and biotransformation. Drug excretion is the removal of the intact drug. Most drugs are excreted by the kidney into the urine. Other pathways include the excretion of drug into bile, sweat, saliva, or milk. Biotransformation (drug metabolism) converts the drug in the body to a metabolite that is excreted more readily. Enzymes involved in biotransformation are located mainly in the liver. Other tissues such as the kidney, lung, small intestine, and skin contain biotransformation enzymes.

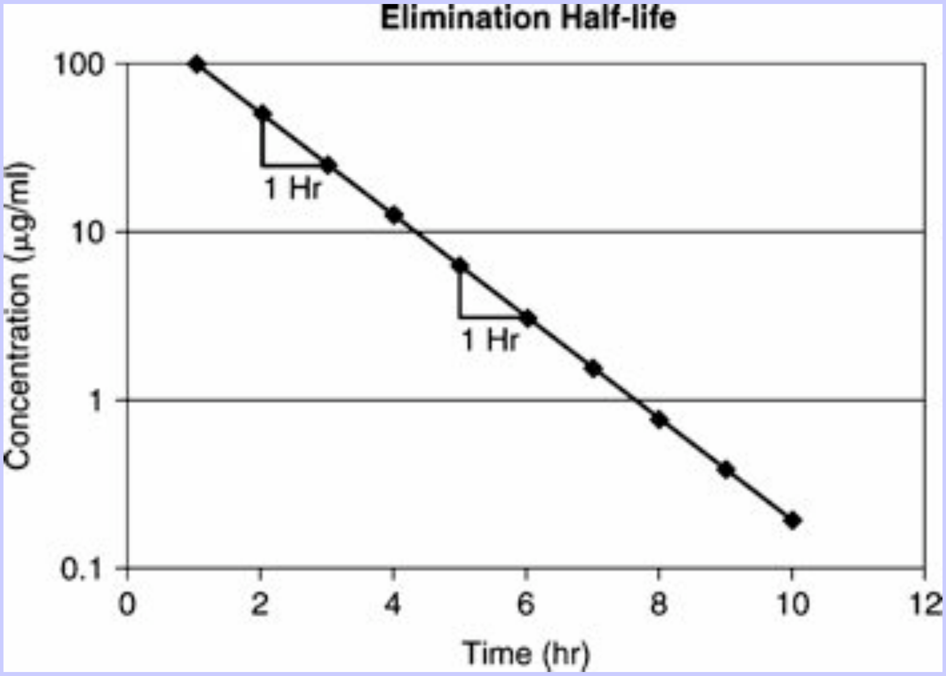
4.1.9 Elimination Rate Constant and Elimination Half-Life

The rate of elimination for most drugs is a first order process. The elimination rate constant K represents the sum of drug elimination by excretion and metabolism. Drug elimination is considered always to occur from the central compartment because the liver and kidney are well perfused tissues. The elimination rate constant is used to calculate the half-life ($T_{1/2}$) of the drug, the time required for drug concentration to decrease by one half (Figure 4.1-7). For first order reactions, $T_{1/2}$ is constant across the plasma concentration versus time curve and is calculated from the following equation:

$$T_{1/2} = 0.693/K$$

where 0.693 = ln2 (the natural logarithm of 2). Mean residence time is the equivalent of $T_{1/2}$ when pharmacokinetics are calculated using statistical moment theory. Mean residence time is actually the time the 175
drug concentration takes to decrease by 63.2%, so the mean residence time value is slightly greater than $T_{1/2}$. The 176
$T_{1/2}$ determines the drug dosage interval, how long a toxic or pharmacologic effect persists, and drug withdrawal times for food animals or performance horses. One should note that elimination of 99.9% of a drug from the plasma requires 10 half-lifes (Table 4.1-1). Knowing the $T_{1/2}$ of a drug gives the clinician some idea of the withdrawal time of the drug and propensity to cause violative drug residues. For drugs that undergo hepatic metabolism (chloramphenicol) or drugs that sequester in specific tissues (aminoglycosides, tetracyclines), simply multiplying the $T_{1/2}$ by a factor of 10 for a withdrawal time may not be sufficient to prevent a violation. One also should note that doubling a drug dose does not double the withdrawal time; it merely adds one half-life to the withdrawal time (Figure 4.1-8).

Figure 4.1-7 For a drug with first order elimination and a half-life of 1 hour, the plasma drug concentration decreases by 50% every hour.



4.1.9.1

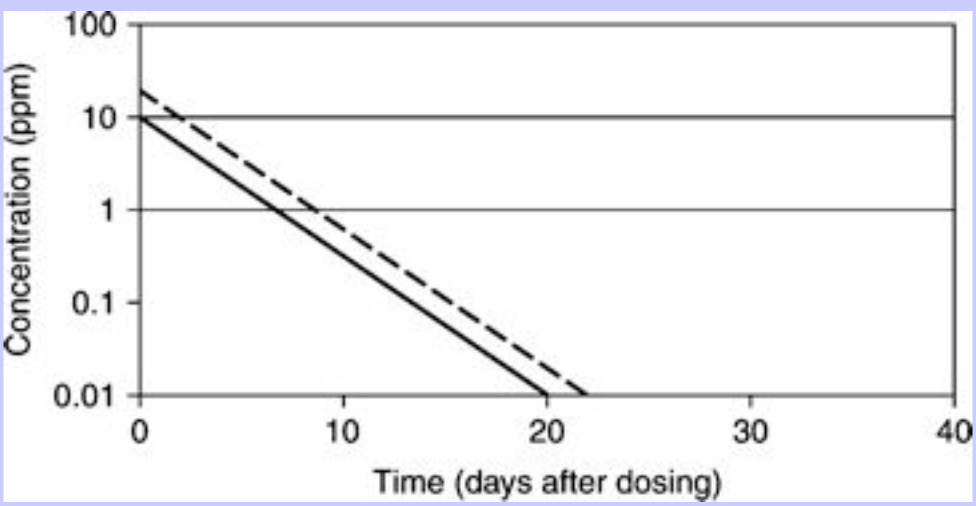
FLIP-FLOP KINETICS

Long-acting drug formulations are often products with carriers that cause them to be absorbed slowly into the systemic circulation. Therefore the drug absorption rate limits the drug elimination rate. The value for K (the elimination rate constant) calculated from the plasma concentration versus time curve is actually the value for Ka (the absorption rate constant). The easiest way to identify “flip-flop” kinetics is to compare the plasma concentration versus time curve for the extravascular route of administration with the curve after the drug is given intravenously (Figure 4.1-9). If the elimination phases of the curves are not parallel, then delayed absorption is prolonging elimination and the flip-flop phenomenon has occurred.

TABLE 4.1-1 Half-Life Elimination of a Drug

NUMBER OF HALF-LIVES	FRACTION OF DRUG REMAINING
0	100%
1	50%
2	25%
3	12.5%
4	6.25%
5	3.125%
6	1.56%
7	0.78%
8	0.39%
9	0.195%
10	0.0975%

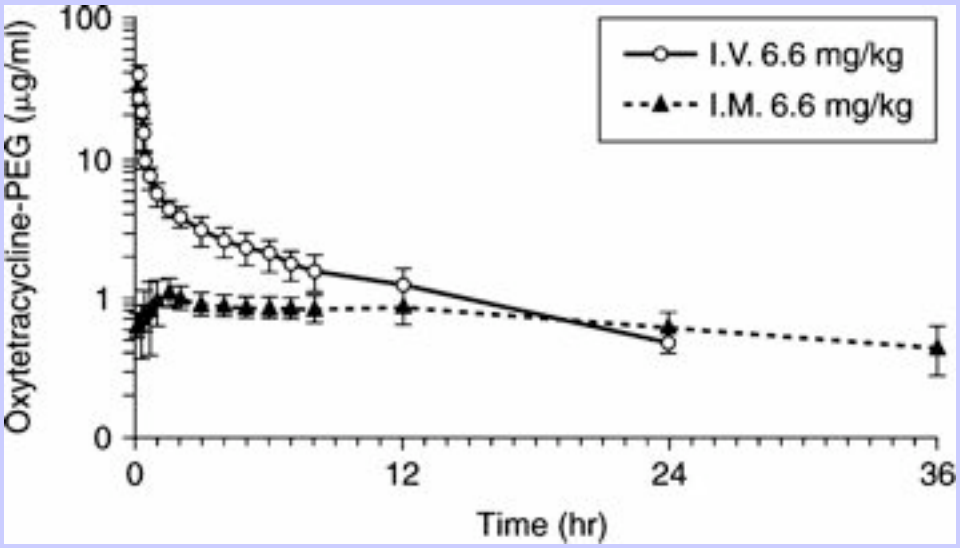
Figure 4.1-8 Doubling a drug dose only adds one half-life to its withdrawal time. Withdrawal times are based on maximum residue limits. For this drug with a half-life of 24 hours, doubling the dose to reach a plasma concentration of 20 ppm results in 21 days instead of 20 days to reach the maximum residue limit of 0.01 ppm.



For a two-compartment model, β (from the equation $C = Ae^{-\alpha t} + Be^{-\beta t}$) is the drug elimination rate constant from the entire body once the drug has reached equilibrium between the two compartments. Therefore, β is used to calculate the elimination half-life:

$$T_{1/2} = 0.693/\beta$$

Figure 4.1-9 Plasma concentration versus time graph for long-acting oxytetracycline demonstrating flip-flop kinetics. The intramuscular route demonstrates the prolonged elimination that results from delayed absorption from the injection site.



176

177

4.1.9.2 CLEARANCE

The parameter clearance (Cl) measures drug elimination from the body without reference to the mechanism of elimination. Cl is the total drug clearance and is the sum of renal clearance (Cl_R), hepatic clearance (Cl_H), and all other elimination mechanisms. The body is considered a compartment of fluid with a definite volume (Vd) in which a drug is dissolved. Cl is the volume of fluid containing drug that is cleared of drug per unit of time (milliliter per minute per kilogram):

$$Cl = (K)(Vd)$$

$$Cl = (0.693/T_{1/2})(Vd)$$

4.1.9.3 RENAL CLEARANCE OF DRUGS

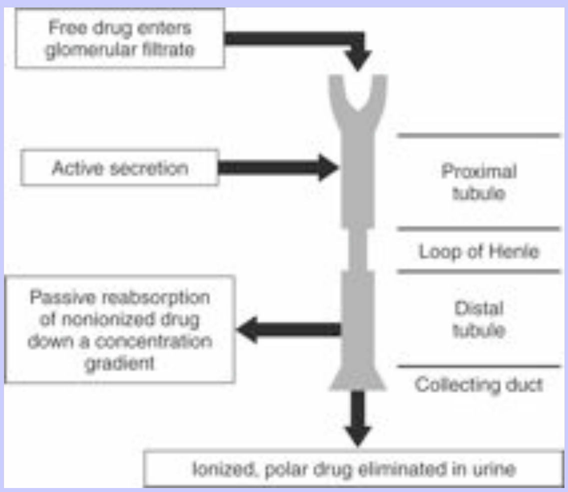
Renal excretion is the major route of elimination from the body for most drugs. Drug disposition by the kidneys includes glomerular filtration, active tubular secretion, and tubular reabsorption (Figure 4.1-10), such that renal drug clearance is defined by the following equation:

$$Cl_R = Cl_F + Cl_S - FR$$

where Cl_R is the total renal clearance, Cl_F is the clearance attributed to glomerular filtration, Cl_S is the clearance attributed to active tubular secretion, and FR is the fraction reabsorbed from the tubule back to circulation.

Glomerular filtration (Cl_F) occurs with small molecules (<300 molecular weight) of free drug (not bound to plasma proteins). Large molecules or protein-bound drugs are not filtered at the glomerulus because of size and electric hindrance. The kidneys receive approximately 25% of cardiac output, so the major driving force for glomerular filtration is the hydrostatic pressure within the glomerular capillaries. Glomerular filtration rate is estimated by measuring a substance or drug that is eliminated only by glomerular filtration, such as creatinine or insulin.

Figure 4.1-10 Movement of drugs in the renal tubule.



If Cl_R is greater than Cl_F, then some tubular secretion is occurring. Active tubular secretion is a carrier-mediated transport system, located in the proximal renal tubule. Such secretion requires energy input because drug is moved against a concentration gradient. Two active tubular secretion systems have been identified: anion secretion for acids and cation secretion for bases. Drugs with similar structures may compete with each other for the same transport system. For example, probenecid competes with penicillin or the fluoroquinolones for the same transport system, effectively decreasing Cl of these antimicrobials.[3] In patients with reduced functional renal tissue, remaining transport systems become saturated easily and drug accumulation occurs.

If Cl_R is less than glomerular filtration rate, then tubular reabsorption of drug is occurring. Tubular reabsorption is an active process for endogenous compounds (vitamins, electrolytes, glucose) and is a passive process for most drugs. Tubular reabsorption occurs along the entire nephron but primarily in the distal renal tubule. Factors that affect reabsorption include the pK_a of the drug, urine pH, lipid solubility, drug size, and urine flow. Drug reabsorption depends highly on ionization, which is determined by the pK_a of the drug and the pH of the urine. According to the Henderson-Hasselbach equation, a drug that is a weak base will be nonionized in alkaline urine and a weak acid will be ionized in alkaline urine. The nonionized form of the drug is more lipid soluble and has greater reabsorption. The pK_a of a drug is constant, but urinary pH is highly

variable in animals and varies with the diet, drug intake, time of day, and systemic acidosis/alkalosis. Species differences can have a major influence on the renal excretion of ionized drugs. Carnivores (with a urine pH of 5.5 to 7.0) have a greater renal excretion of basic drugs than herbivores (with a urine pH of 7.0 to 8.0).

4.1.9.4 HEPATIC CLEARANCE OF DRUGS

Nonrenal drug elimination is assumed to be caused primarily by biotransformation (hepatic metabolism) and biliary excretion. Clearance of a drug by the liver is determined by hepatic blood flow (Q_H) and the intrinsic ability of the liver to extract the drug (extraction ratio or ER_H):

$$Cl_H = (Q_H)(ER_H)$$

Drugs with a high extraction ratio (approaching 1) have Cl_H equal to the hepatic blood flow. These drugs are called *high clearance drugs*. Examples of drugs with high ER_H are lidocaine, propranolol, and isoproterenol. 177

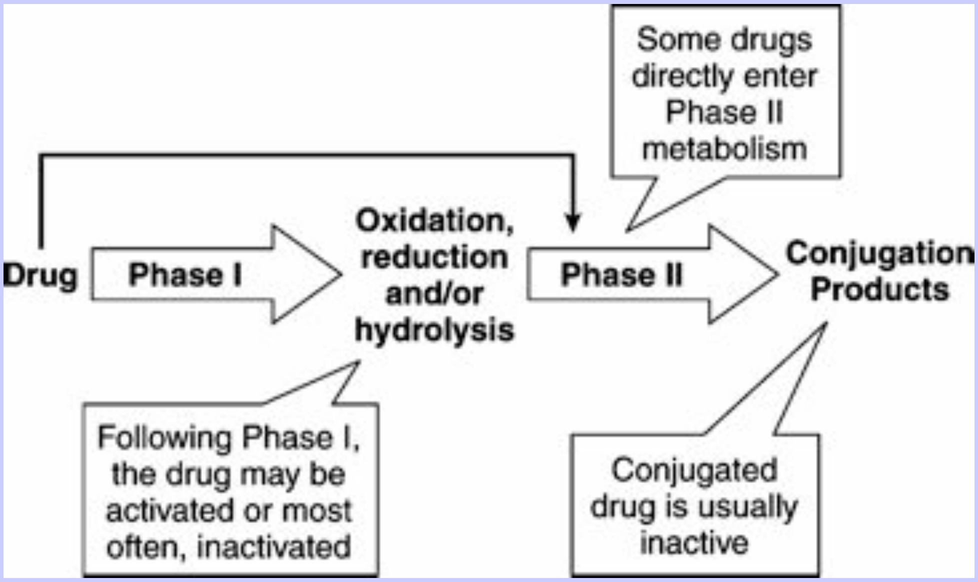
Changes in hepatic blood flow greatly influence clearance of drugs with high ER_H. Lidocaine, an antiarrhythmic drug, has an average Cl of 21 ml/min/kg after intravenous administration in dogs. Hepatic plasma flow in dogs is 20 to 26 ml/min/kg. Lidocaine is not eliminated by any other route; therefore the clearance of lidocaine is almost identical to hepatic blood flow.[4] Drugs that are administered orally and are absorbed across the intestinal mucosa must first pass through the liver via the portal circulation before being distributed to the rest of the body. Most of a drug with a high ER_H is cleared in one pass through the liver; this is called the *first pass effect*, and it limits the oral administration of many drugs. 178

Drugs that have a low hepatic extraction rate ($ER_H \leq 0.2$) are not affected greatly by changes in hepatic blood flow. However, changes in the hepatic microsomal enzyme systems and protein binding do affect their clearance. A first pass effect does not interfere with the systemic availability of these drugs. Drugs with a low ER_H include chloramphenicol, phenylbutazone, phenobarbital, and digoxin.

4.1.9.5 BIOTRANSFORMATION (HEPATIC METABOLISM) OF DRUGS

Metabolism is necessary for removal of lipophilic drugs from the body (Figure 4.1-11). Biotransformation depends on the chemical composition of the liver, activity of major drug metabolism enzymes, hepatic volume (perfusion rate), drug accessibility to and extraction by hepatic metabolic sites, and physicochemical properties of the drug. Biotransformation of a parent drugs results in metabolites that may be active or inactive themselves. A *prodrug* is a drug administered in an inactive form that must be biotransformed to its active form. Drug metabolic pathways have been divided into *phase I* and *phase II* reactions. Phase I reactions (oxidation, reduction, hydrolysis, hydration, dehioacetylation, and isomerization) typically add functional groups to the drug molecule necessary for phase II reactions. Phase II reactions (glucuronidation, glucosidation, sulfation, methylation, acetylation, amino acid conjugation, glutathione conjugation, and fatty acid conjugation) typically include conjugation reactions that increase the water solubility of the drug, facilitating its excretion from the body.

Figure 4.1-11 Hepatic metabolism of drugs.



Among the reactions catalyzed by drug metabolism enzymes, the cytochrome P-450 mixed-function oxidase system is the most intensively studied. This reaction catalyzes the hydroxylation of hundreds of structurally diverse drugs the only common characteristic of which is high lipid solubility. Species differences in drug metabolic rate are the primary source of variation in drug activity and toxicity. Cats have a poor ability to glucuronidate drugs, pigs are deficient in sulfate conjugation, and dogs are poor acetylators.

4.1.9.6

INDUCTION AND INHIBITION OF METABOLISM

Enzyme induction or inhibition by other drugs or chemicals can affect metabolism of drugs substantially (Box 4.1-4). In some cases the drug itself may alter its own metabolic rate by induction or inhibition. Many drugs are capable of inducing enzyme activity, thereby increasing the rate of metabolism and hepatic clearance of concurrently administered drugs, typically resulting in a decreased pharmacologic effect. Enzyme induction typically occurs slowly, requiring several weeks to reach maximum effect. Increased hepatic RNA and protein synthesis and increased hepatic weight accompany induction. Enzyme induction is important in the 178
pathogenesis of hepatotoxicity and therapeutic failure of many drugs. Phenobarbital is a potent enzyme 179
inducer, known for hepatotoxicity and for inducing its own metabolism.

4.1.9.6.1

BOX 4.1-4 DRUGS THAT AFFECT ENZYME FUNCTION

4.1.9.6.1.1

Enzyme Inducers

Chlorinated hydrocarbons

Griseofulvin

Phenobarbital

Phenylbutazone

Phenytoin

Rifampin

4.1.9.6.1.2

Enzyme Inhibitors

Chloramphenicol

Cimetidine

Erythromycin

Fluoroquinolones

Ketoconazole

Phenylbutazone

Prednisolone

Quinidine

Drug-induced enzyme inhibition also occurs and typically results in prolonged clearance of a concurrently administered drug. The potential for toxicity or for an exaggerated pharmacologic response increases. In contrast to induction, inhibition occurs rapidly. Erythromycin and enrofloxacin are known inhibitors of the metabolism of theophylline; concurrent administration can cause seizures.[5,6]

4.1.9.7

KINETICS OF DRUG METABOLISM

The enzymes that catalyze drug metabolism typically obey Michaelis-Menten kinetics as a *first order reaction:*

$$V = \frac{V_{max}[C]}{K_m + [C]}$$

where V is the rate of drug metabolism, K_m is the Michaelis constant, and C is the drug concentration. In most clinical situations, the drug concentration is much less than the Michaelis constant, so the equation reduces to the following:

$$V = \frac{V_{max}[C]}{K_m}$$

that is, the rate of drug metabolism is directly proportional to the concentration of free drug, and first order kinetics are observed in that a constant fraction of drug is metabolized per unit of time.

With a few drugs—such as phenylbutazone, ethanol, and phenytoin—or if large doses of a drug are given, the drug concentrations achieved are much greater than K_m and the rate equation becomes the following:

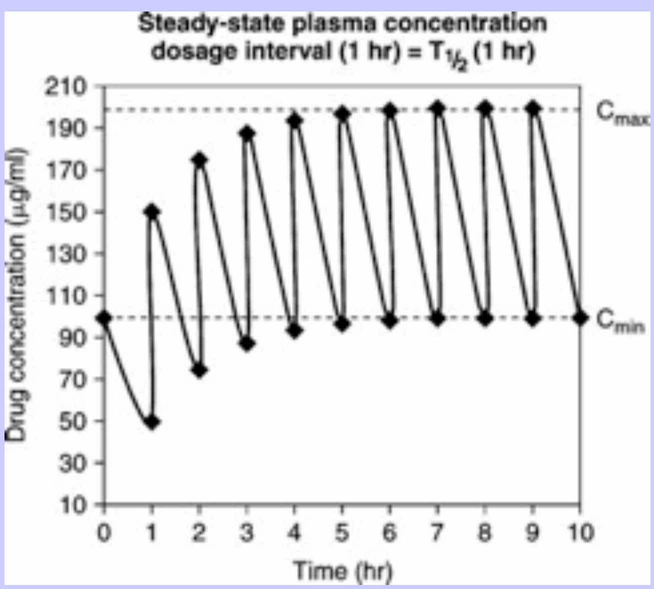
$$V = \frac{V_{max}[C]}{[C]} = V_{max}$$

The enzymes are saturated by the high free drug concentrations, and the rate of metabolism remains constant over time. This is *zero order kinetics* or *nonlinear kinetics*, and a constant amount of drug is metabolized per unit of time.

4.1.10 Drug Accumulation

Drugs often are given in multiple-dosage regimens. To predict plasma drug levels, one must decide whether successive doses of a drug will have any effect on the previous dose. The *principle of superposition* assumes that early doses of drug do not affect the pharmacokinetics of subsequent doses. For most drugs, as equal doses are given at a constant dosage interval, the plasma concentration–time curve plateaus to reach a steady state. At steady state the plasma drug concentrations fluctuate between a maximum concentration (C_{max} or peak) and minimum concentration (C_{min} or trough). Once the drug concentration reaches steady state, C_{max} and C_{min} are constant and remain unchanged from dose to dose (Figure 4.1-12). The time to steady state depends solely on the elimination $T_{½}$. Approximately six half-lives occur to reach 99% steady state levels. The drug dose and dosage frequency influence the values of C_{max} and C_{min} at steady state, whereas the dosage frequency and $T_{½}$ influence the fluctuation between C_{max} and C_{min}.

Figure 4.1-12 Plasma concentration versus time graph for an intravenous drug that produces a peak plasma concentration of 100 μg/ml after a single dose. After 6 hours (which equals six half-lives), the maximum and minimum serum drug concentration become constant and further drug accumulation does not occur. This is steady state.



4.1.10.1

CLINICAL CONSEQUENCES OF DOSAGE INTERVALS LESS THAN THE HALF-LIFE

Drugs such as phenobarbital, potassium bromide, phenylbutazone, and digoxin commonly are given at dosage intervals much shorter than their half-lives (Figure 4.1-13), resulting in a C_{max} at steady state that is greater than the peak concentration after a single dose. Minimal fluctuation occurs between C_{max} and C_{min}, and missing a single dose does not affect plasma concentrations greatly. A lag time to reach the desired plasma concentrations occurs at steady state, and a lag time for plasma concentrations to change in response to a dose change also occurs.

4.1.10.2

CLINICAL CONSEQUENCES OF DOSAGE INTERVALS GREATER THAN THE HALF-LIFE

Drugs such as intravenous formulations of penicillin and cephalosporins are administered at dosage intervals greater than the $T_{½}$ (Figure 4.1-14). As the dosage interval increases, C_{max} at steady state is closer in value to 179
the peak concentration of a single dose. If the dosage interval is greater than 10 half-lives (the time required to 180
eliminate 99.9% of the previous dose), drug accumulation essentially does not occur. Great fluctuation occurs between C_{max} and C_{min} (peak and trough), and missing a dose greatly affects plasma concentrations. However, minimal lag time to achieve the desired plasma concentration occurs.

Figure 4.1-13 Plasma concentration versus time graph for drug with a dosage interval (0.5 hour) less than the half-life (1 hour), demonstrating significant drug accumulation.

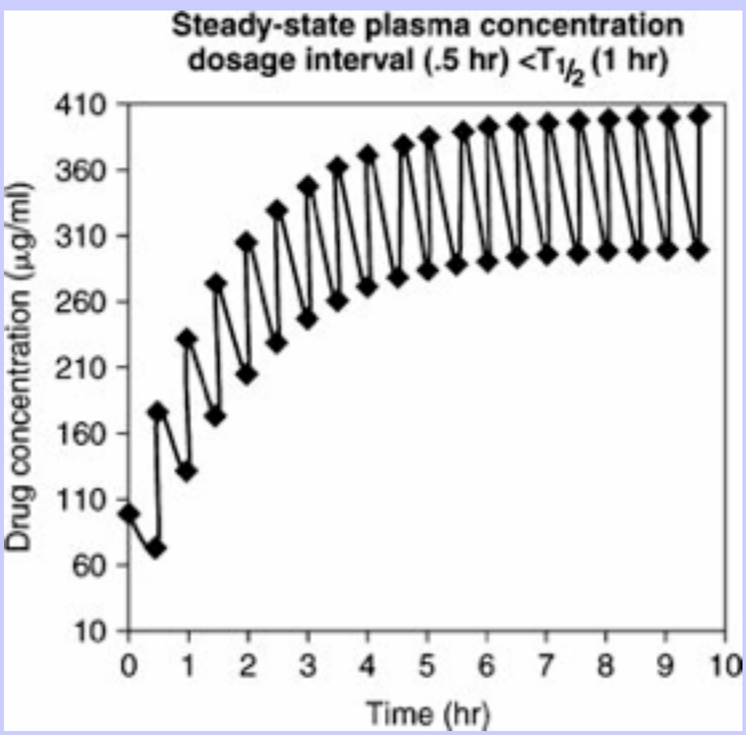


Figure 4.1-14 Plasma concentration versus time graph for a drug with a dosage interval (4 hours) greater than the half-life (1 hour), resulting in no significant drug accumulation.

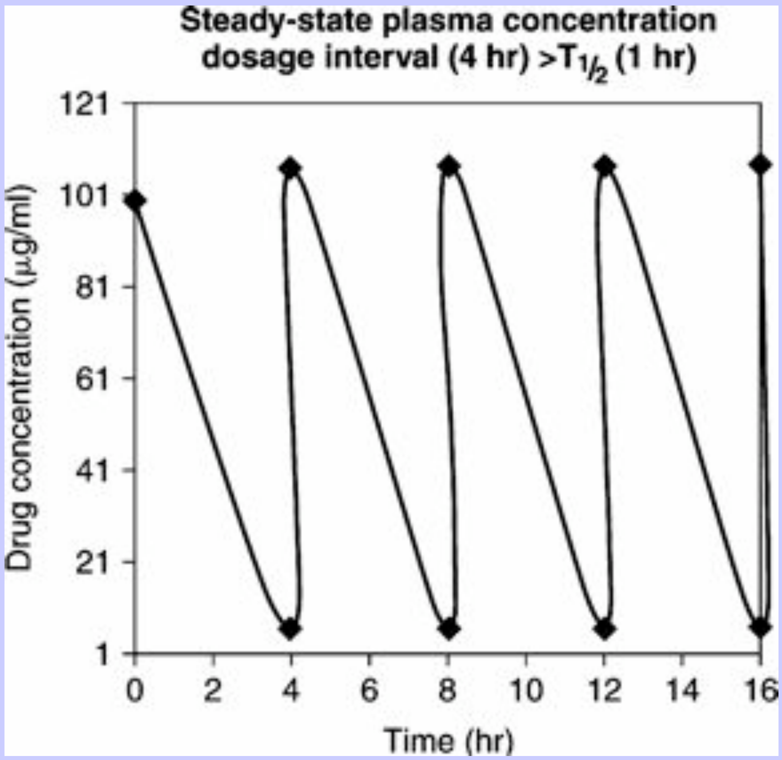


4.1.11 Designing Drug Dosage Regimens

The success of drug therapy depends greatly on the dosage regimen design. Not all drugs need rigid individualization of the dosage regimen. In the case of antimicrobials with a broad safety range, such as the penicillins and cephalosporins, the dosage is not titrated precisely but rather is based on clinical judgment to maintain an effective plasma concentration above the minimum inhibitory concentration for the bacterial pathogen. For drugs with narrow therapeutic margins such as digoxin, the aminoglycosides, and theophylline, the individualization of the dosage regimen is important. The objective of the dosage regimen for these drugs is to produce a safe plasma drug concentration that does not exceed the minimum toxic concentration or fall below a critical minimum concentration at which the drug is not effective. Factors that influence the concentration of drug attained at the site of action include the dose administered, the route of administration, release and absorption of drug from dosage form, the extent of drug distribution, and the rate of drug elimination.

Age of the animal may have a profound effect on drug disposition (Table 4.1-2).[7] The definition of *geriatric* varies between species, and in small animals the definition varies between breeds. Body composition and regional blood flow change in aged animals. Cardiac output decreases, so regional and organ blood flow also decreases. These changes affect drug absorption, distribution, and elimination. Blood flow is redistributed preferentially to the brain and heart, so the risk of drug toxicity increases in these organs. Gastrointestinal

motility and absorptive capacity decrease. Hepatocyte number and function decrease along with hepatic and splanchnic blood flow. As renal blood flow decreases, glomerular filtration rate and active secretory capacity of the nephron decrease, resulting in decreased renal clearance of drugs. Lean body mass decreases, whereas fatty tissues increase. Increased body fat results in a decrease in total body water and cell mass. The plasma concentrations of water-soluble (low volume of distribution) drugs tend to increase, whereas the plasma concentrations of lipid-soluble (high volume of distribution) drugs tend to decrease. Serum albumin decreases, whereas γ-globulins increase, so that total plasma protein concentrations remain the same. Concentrations of unbound drug for drugs that normally bind to albumin increase, such as for the nonsteroidal antiinflammatory drugs.

TABLE 4.1-2 Age-Related Changes in Geriatric and Pediatric Patients

BODY PART/FUNCTION AFFECTED	GERIATRIC	PEDIATRIC
Organ blood flow	Decrease	Increase
Total body water	Decrease	Great increase
Body fat	Increase	Decrease
Serum proteins	Decrease in albumin	Decrease in albumin
	Increase in globulins	
Hepatic metabolism	Decrease	Great decrease

180

181

The definition of *pediatric* also varies with species and age, but all the determinants of drug disposition are altered as the animal matures. Blood flow to the heart and brain is greater and faster, making the pediatric patient more susceptible to drug-induced cardiotoxicity and neurotoxicity. Gastrointestinal absorption tends to decrease because of decreased gastric emptying and decreased intestinal peristalsis. Absorption from intramuscular and subcutaneous sites changes as muscle mass and blood flow change. Neonates have less fat and greater total body water (primarily ECF) than adults. Therefore low Vd drugs distribute into a large volume, requiring an increase in the dose to avoid therapeutic failure. Because of low body fat, lipid soluble drugs have higher plasma concentrations. Drug elimination by hepatic metabolism and renal excretion is limited in pediatric animals.

The sick animal usually has impaired drug detoxifying ability. Hepatic damage reduces drug metabolism and may increase drug action, whereas renal damage and impaired excretion decrease drug clearance. Alterations in gastrointestinal motility affect drug absorption. Decreased plasma proteins increase free drug available for effect. Peripheral circulation decreases in shock and decreases absorption of intramuscularly and subcutaneously administered drugs.

4.1.11.1 PHARMACOKINETIC-BASED DOSAGE REGIMENS

A drug dose regimen is composed of a dose and a dosing frequency. Some drugs are given as single doses, so a specific plasma concentration is targeted. When giving multiple doses of a drug, one must consider the dosage frequency and drug accumulation. Simple calculations can be used to design a patient-specific dose regimen.

4.1.11.2
SINGLE-DOSE REGIMEN

A single drug dose has its duration of action determined by the size of the dose, the elimination rate constant, and the volume of distribution. To calculate a single dose of a drug or when assuming a once a day dosing, one needs only the Vd and the desired plasma concentration:

$$\mathrm{Dose} = (\mathrm{Vd})(C_0)$$

For drugs administered by routes other than intravenously, one must remember to correct for bioavailability:

$$\mathrm{Dose} = (\mathrm{Vd})(C_0)/(F)$$

4.1.11.3
CONTINUOUS INTRAVENOUS INFUSION RATE

When the desired response needs to be constant, a drug may be infused at a constant rate following the initial intravenous dose:

$$R = (C)(\mathrm{Vd})(K)$$

R (rate) is essentially the rate of drug loss from the body (milligrams per minute or per hour). So to maintain the established concentration of drug in the body, infusing the drug at the rate equal to its loss (K is the elimination rate) is necessary. For example, the vasopressive drugs dopamine and dobutamine have short elimination half-lives, so they must be administered by constant infusion.

4.1.11.4
MULTIPLE-DOSE REGIMEN

Continuous intravenous infusion offers the most precise control of drug levels in the body and is essential for precise control of drugs with a narrow safety margin or rapid elimination. Continuous intravenous infusion is not feasible for most drugs in veterinary medicine. Maintaining an average desired plasma concentration is possible by repeating doses at constant dosing intervals. Obviously, the highest plasma concentrations occur soon after drug administration and the lowest concentrations occur just before the next dose is administered. As long as the lowest concentration is acceptable for therapy, and the highest concentration does not cause toxicity, these variations in plasma concentration are acceptable.

$$\mathrm{Dose} = \frac{(C_{ave})(V_d)(\tau)}{(1.44)T_{1/2}}$$

where ι is the dosage interval and 1.44 is a constant to correct for logarithmic scale.

4.1.11.5
LOADING DOSE FOLLOWED BY MAINTENANCE DOSE REGIMEN

Drugs that have long elimination half-lives such as digoxin and the sulfonamides have a long lag time to acceptable drug concentrations; therefore they usually are given by a large loading dose followed by maintenance doses:

$$\mathrm{Dose}_L = \frac{\mathrm{Dose}_M}{1-e^{-K\tau}}$$

4.1.12 Therapeutic Drug Monitoring

The monitoring of plasma drug concentrations is valuable if a relationship exists between the plasma drug concentration and the desired clinical effect or between the plasma drug concentration and an adverse effect. Monitoring is particularly helpful in patients with gastrointestinal, cardiovascular, hepatic, or renal disease and also is useful when many drugs are being administered at the same time and may be altering the metabolic fate of each other. Therapeutic drug monitoring (TDM) is often valuable for regulating the dosage of drugs used chronically or prophylactically.

For those drugs in which plasma concentration and clinical effect are not related, one may monitor other 181
pharmacodynamic parameters. For example, one may measure clotting times in patients given anticoagulant 182
therapy. From the plasma drug concentration data and patient observations, the clinician then may adjust the dosage regimen. Therapeutic drug monitoring in veterinary medicine is done most commonly for digoxin, phenobarbital, gentamicin, and amikacin. The drugs for which TDM commonly is used are characterized by serious toxicity (digoxin, phenobarbital); a steep dose-response curve in which a small increase in dose can cause a significant increase or decrease in response (theophylline); significant pharmacokinetic variability between individual patients so that dose is poorly predictive of plasma drug concentration; easily saturated elimination mechanisms that lead to nonlinear kinetics; or the cost of therapy justifies confirming a desired plasma drug concentration (Table 4.1-3).

4.1.12.1 PERFORMANCE OF THERAPEUTIC DRUG MONITORING

The clinician should not submit samples for TDM until plasma drug concentrations have reached steady state in the patient, so most drug monitoring occurs after six elimination half-lives have passed. For conditions in which steady state concentrations must be reached immediately, the clinician can administer a loading dose. The risk of adverse drug reactions obviously increases, so the clinician can use TDM to determine proactively the proper maintenance dose. When administering a loading dose, the clinician should perform TDM after the loading dose to establish a baseline. Taking a second sample one drug half-life later ensures that the maintenance dose is able to maintain the concentrations achieved by the loading dose. If the drug concentrations at the second sample do not match the first sample, the clinician can adjust the maintenance dose at this time rather than waiting for steady state, with the risk of therapeutic failure or toxicity. The third time for TDM is at steady state.

TABLE 4.1-3 Recommendations for Therapeutic Drug Monitoring

DRUG	THERAPEUTIC RANGE	VOLUME OF DISTRIBUTION (L/kg)	HALF-LIFE	TIME TO STEADY STATE	SAMPLE COLLECTION
Amikacin	25 µg/ml peak	0.25	1–2 hours	1 day	Peak: 1 hour after administration
	<5 µg/ml trough				Trough: Just before next dose
					Collect sample in plastic only.
Bromide	Monotherapy:	–	24 days	4 months	Anytime
	2–3 µg/ml				
	(20–30 mmol/L)				
	With phenobarbitol:				
	1–2 g/ml				
	(10–20 mmol/L)				
Digoxin	0.9–3.0 ng/ml	6.7	23 hours	7 days	2–5 hours after dose Collect sample in glass only.
Gentamicin	10 µg/ml peak	0.3	1 hour	1 day	Peak: 1 hour after administration
	<2 g/ml trough				Trough: Just before next dose
Phenobarbital	14–45 µg/ml	0.96	24 hours	6 days	Anytime
	(70–170 µmol/L)				
Theophylline	10–20 µg/ml	0.8	13 hours	3 days	1–2 hours after dose

The number of samples collected for TDM depends on the drug, its $T_{½}$, and the reason for monitoring. Determining optimal aminoglycoside therapy requires C_{max} and C_{min} samples. No statistically significant difference occurs between C_{max} and C_{min} values for phenobarbital or potassium bromide in most animals when they are administered twice a day, so one can collect a single sample for TDM without regard for when the sample is taken during the dosing interval. However, one should collect C_{max} and C_{min} samples in any patient not responding as expected to therapy to determine if the individual has a shorter or longer elimination half-life than normal for the drug (Box 4.1-5). 182

4.1.12.1.1 BOX 4.1-5 INTERPRETING THE RESULTS OF THERAPEUTIC DRUG MONITORING

4.1.12.1.1.1 Plasma Concentrations Lower Than Anticipated

Poor compliance with regimen

Error in dosage regimen

Wrong drug product (controlled release instead of immediate release)

Poor bioavailability

Rapid elimination

Increased apparent volume of distribution

Steady state not reached

Poor timing of blood sample

4.1.12.1.1.2 Plasma Concentrations Higher Than Anticipated

Poor compliance with regimen

Error in dosage regimen

Rapid bioavailability

Decreased apparent volume of distribution

Slow elimination

4.1.12.1.1.3 Plasma Concentration Correct but Patient Does Not Respond to Therapy

Incorrect diagnosis of patient

Altered tissue receptor

Sensitivity (tolerance)

Drug interaction at receptor site

4.1.12.2 ADJUSTMENT OF DOSAGE REGIMENS

Adjusting the dosage regimen frequently is required as one administers drugs to diseased animals, because the dosage regimens have been worked out in healthy, normal animals. Adjustment is indicated when drug elimination or the volume of drug distribution alters significantly in the animal. In general the following are true:

- If the volume of distribution changes, one must change the drug dose.
- If the elimination half-life of the drug changes, one must change the dosing interval.

For drug dosage regimens determined by TDM, one makes modifications based on a percentage:

$$\text{New Dose} = \text{Old Dose} \times (\text{Target Concentration} \div \text{Measured Concentration})$$

4.1.13 Adjustments in Renal Failure

The ultimate route for drug elimination from the body is the kidney. Therefore that renal disease profoundly affects the disposition of drugs administered to animal in renal failure is not surprising. With reduced renal clearance, the parent drug and/or its metabolites may accumulate in the patient and cause toxicity. Loss of proteins and electrolytes in urine and the alterations in acid-base balance associated with renal failure affect the pharmacokinetics and pharmacodynamics of drugs. Enhanced drug activity or toxicity can occur because of synergy with uremic complications. Altogether these effects make determining safe and effective drug dosages difficult for veterinary patients in renal failure.

4.1.13.1 BIOAVAILABILITY AND ABSORPTION OF DRUGS

Uremic patients exhibit delayed gastric emptying, which may delay the oral absorption of some drugs.[8] Renal failure also may affect the absorptive capacity of the small intestine.[9] Gastrointestinal symptoms such as nausea, vomiting, and diarrhea are common in uremic patients and may affect drug absorption. Concomitant administration of antacids or phosphate-binding drugs, which commonly are administered to renal failure patients, may decrease drugs with pH-dependent bioavailability.[8] The fluoroquinolones, tetracyclines, ampicillin, and sulfonamides are examples of antimicrobials that have reduced bioavailability when administered with antacids.

4.1.13.2 DISTRIBUTION OF DRUGS

The Vd of many drugs changes in patients with renal failure. Fluid retention is often a characteristic of renal failure, and the consequent change in body water alters the Vd of drugs that are distributed predominantly to extracellular water, such as penicillins, cephalosporins, aminoglycosides, and nonsteroidal antiinflammatory drugs. A significant reduction in the degree of protein binding of many drugs also occurs, which is more than can be explained by the hypoalbuminemia that occurs in many glomerular diseases.[10] Conformational change in the albumin molecule is thought to be caused by uremic toxins that reduce the degree of drug binding. The accumulation of organic molecules that displace acidic drugs from their albumin binding sites also alters protein binding of these drugs. Protein binding of basic drugs tends to be normal in renal failure patients.[11] The increase in unbound drug increases the Vd, and drugs cleared only by glomerular filtration actually have an increased clearance rate. Although determining the absolute changes in protein binding in an individual patient is difficult, clinicians must realize that they can achieve therapeutic concentrations of many drugs in renal failure patients at lower than normal therapeutic concentrations of these drugs in normal animals.

Distributional changes also have been documented for drugs that are not highly protein bound.[9] Such changes may be due to changes in binding to tissues. The clinical significance of distributional changes in animals with 183
renal failure is not known, and dosage adjustments may be necessary only with drugs that are highly protein 184

bound (>99%) and are excreted primarily in the urine. Of the antimicrobials, only ceftiofur and some sulfonamides are this highly protein bound, but anticoagulants like warfarin (coumarin) and almost all nonsteroidal antiinflammatory drugs are highly protein bound. Because pharmacologic action is caused by the unbound, free drug fraction, small changes in binding of these drugs greatly increase the free drug available for such action and can have dramatic clinical consequences and should be considered when one develops treatment plans.

4.1.13.3

HEPATIC METABOLISM

Hepatic metabolism of some drugs is altered during renal insufficiency, and this effect varies considerably between species. Glycine conjugation, acetylation, and hydrolytic reactions generally are slowed in uremia. Uremia does not seem to affect glucuronide synthesis, sulfate conjugation, or methylation pathways.[12] The metabolism of cephalothin, cortisol, insulin, procaine, procainamide, salicylate, and some sulfonamides decreases in uremic human beings,[8] resulting in drug accumulation if the overall drug elimination rate decreases. The formation of renally eliminated drug metabolites is also important in renal failure patients, because some metabolites are pharmacologically active.[13] For example, enrofloxacin undergoes some hepatic metabolism to ciprofloxacin, which has greater antimicrobial activity than enrofloxacin against *Pseudomonas* spp. The high incidence of adverse drug reactions in renal failure patients is attributed in part to the accumulation of toxic metabolites. The acetylation metabolites of sulfonamides are not antimicrobially active but retain the toxicity of the parent drugs.

4.1.13.4

METABOLIC BALANCE

The uremic patient is often in a state of altered acid-base balance, electrolyte derangement, and fluid depletion. Administration of sodium- or potassium-containing antimicrobials such as sodium ampicillin or potassium penicillin may result in serious sodium overload and potassium induced neuronal disturbances. Administration of antacids, enemas, or laxatives may cause magnesium, aluminum, or phosphate intoxication. Acidosis, which occurs commonly in uremic patients, increases the free drug concentrations of some drugs such as salicylate and phenobarbital, thereby increasing drug concentrations in the central nervous system. Acidosis also increases ionic binding of the aminoglycosides, increasing accumulation in the renal tubular epithelium and enhancing nephrotoxicity. Uremic complications also may enhance drug toxicity. Uremia-induced functional changes in gastrointestinal and nervous system tissues allow adverse reactions to be induced more easily. The blood-brain barrier is altered in uremia, allowing greater drug concentrations in the central nervous system. The anabolic effect of tetracyclines and the catabolic effect of corticosteroids may worsen azotemia.[10]

4.1.13.5

DOSAGE ADJUSTMENTS

The goal of dosage adjustment is to provide a drug concentration–time profile in the renal failure patient that is as similar as possible to a normal patient. The best approach to modifying drug therapy in renal failure patients is to carry out therapeutic drug monitoring and adjust the dosage for each patient. This is possible with some drugs, such as gentamicin and amikacin, but is impractical and cost-prohibitive for most drugs used in veterinary practice. The best approach for most drugs is to estimate a corrected dose from available renal function tests and then to monitor the patient closely for evidence of efficacy or toxicity. For drugs eliminated primarily by renal mechanisms, creatinine clearance correlates well with drug clearance. Creatinine is an endogenous product of creatinine phosphate metabolism in muscle and is removed by glomerular filtration, and serum concentrations are relatively constant in healthy persons and animals. The elimination $T_{1/2}$ of a drug

eliminated in urine remains stable until creatinine clearance is reduced to 30% to 40% of normal, which is why drug dosage regimens typically are not adjusted until two thirds of renal function has been lost. In human patients, creatinine clearance is quantified by determining urinary creatinine excretion over 24 hours. The measured creatinine clearance then is used in formulae to make drug dosage adjustments. Unlike in human medicine, values for creatinine clearance are not usually available for veterinary patients. When creatinine clearance is not available, a single value of the patient's serum creatinine can be substituted into the formulae. However, the relationship between serum creatinine is not linear once serum creatinine is greater than 4 mg/dl, so the adjustment formulae are even less accurate for predicting an ideal dose adjustment.[10] These formulae do not account for changes in the volume of distribution, degree of protein binding, and nonrenal clearance mechanisms of the drug that may be caused by the renal dysfunction. Therefore one must regard these dosage adjustments as preliminary estimations to be followed by adjustments based on observed clinical response.

With the dose-reduction method, one adjusts the normal dosage regimen by reducing the drug dose and maintaining the drug dosing interval:

$$\text{Adjusted Dose} = \text{Normal Dose} \times (\text{Patient's Cr Clearance}/\text{Normal Cr Clearance})$$

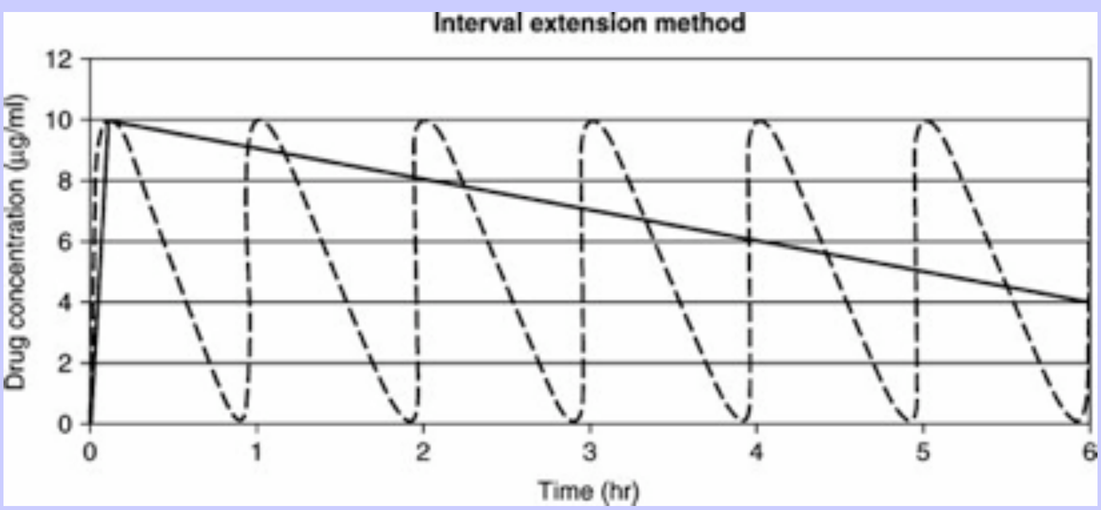
or

$$\text{Adjusted Dose} = \text{Normal Dose} \times (\text{Normal Cr}/\text{Patient's Cr})$$

where Cr is creatinine. 184

185

Figure 4.1-15 Comparison of an interval extension dosage regimen *(solid line)* in a renal failure patient with a normal dosage regimen in a healthy patient *(dotted line)*. Normal elimination half-life was 15 minutes; in the renal failure patient half-life increased to 8 hours.



With the interval extension method, one maintains the drug dose and extends the drug dosing interval:

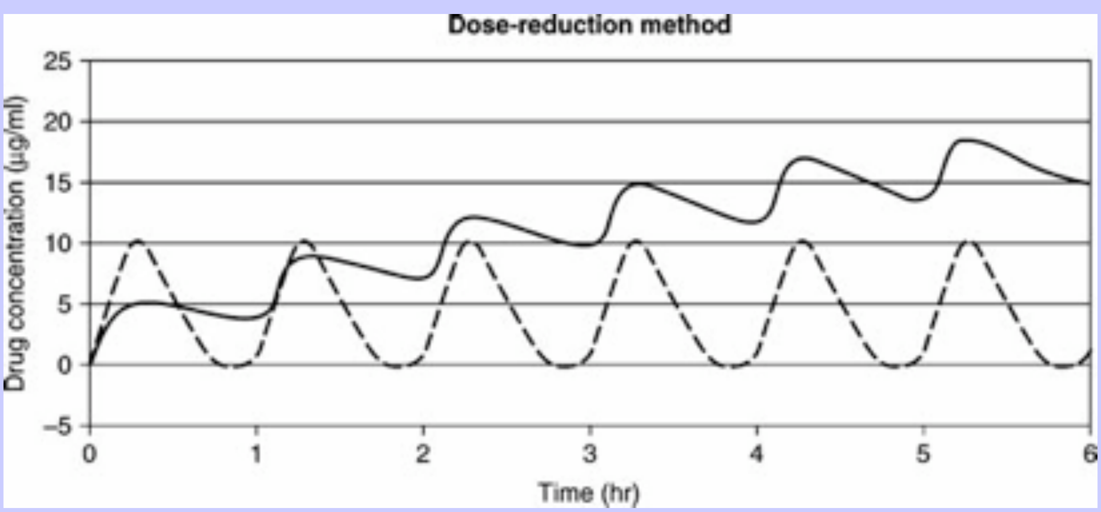
$$\text{Adjusted Interval} = \text{Normal Interval } [1/(\text{Patient's Cr Clearance}/\text{Normal Cr Clearance})]$$

or

$$\text{Adjusted Interval} = \text{Normal Interval } [1/(\text{Normal Serum Cr}/\text{Patient's Serum Cr})]$$

Both methods attempt to keep the average plasma drug concentrations constant. The interval extension method produces C_{max} and C_{min} values similar to that seen in healthy patients (Figure 4.1-15), but it does produce substantial periods of time during which drug concentrations may be subtherapeutic. Interval extension is the preferred method with aminoglycosides, which have a long postantibiotic effect and for which a low trough concentration is desirable to reduce the risk of nephrotoxicity. Depending on the relationship of the elimination $T_{1/2}$ to the dosage interval, significant drug accumulation may occur with the dose-reduction method (Figure 4.1-16), but at steady state no periods of time occur during which concentrations are subtherapeutic.[14] Dose reduction is the preferred method for the penicillin and cephalosporin antibiotics, for which maintaining the plasma concentration above the minimum inhibitory concentration of the pathogen correlates with efficacy and the drugs are relatively nontoxic even if accumulation occurs. To decide which method to use, the practitioner should determine if drug efficacy and toxicity are related to peak, trough, or average plasma concentrations and then should select the method that balances efficacy against potential 185
toxicity. The interval extension method is more client convenient, because one simply administers the normal 186
recommended dose less frequently. And if the drugs are available only in fixed dosage forms (e.g., capsules or unbreakable tablets), adjusting the dosage interval is easier.

Figure 4.1-16 Comparison of dose-reduction dosage regimen in renal failure patient *(solid line)* with normal dosage regimen in a healthy patient *(dotted line)*. Normal elimination half-life was 15 minutes; in the renal failure patient half-life increased to 8 hours.



Because the elimination half-life is prolonged in patients with renal disease and because six elimination half-lives always are required to reach 99% of steady state concentrations, a delay occurs in reaching steady state in renal failure patients compared with animals with normal renal function. Therefore the clinician may need to administer a loading dose to achieve therapeutic drug concentrations rapidly. For the dose-reduction method one achieves this by giving the usual dose initially, followed by the reduced dose the next time. For the interval extension method one achieves therapeutic drug concentrations by giving a double dose initially.

For renal failure patients in general one must consider the following:

1. One should avoid using any drugs at all unless definite therapeutic indications exist. If one must use a drug, one should try to select one that is metabolized hepatically and excreted in bile rather than eliminated by the kidneys (e.g., doxycycline).

2. If therapeutic drug monitoring is available, one should tailor the drug dosage regimen to that specific patient.

3. If therapeutic drug monitoring is unavailable, one should determine if clinically proven, adjusted dosage regimens are available for specific drugs. The package insert on human pharmaceuticals often gives guidelines for adjusting dosages.

4. If the drug has not been studied sufficiently to have dosage adjustment recommendations, one should determine whether sufficient information exists about its kinetics to estimate the proper drug dose in renal failure.

5. One should carefully monitor treated patients for signs of efficacy and toxicity.

4.2

4.2—Antimicrobial Therapy

Patricia M. Dowling

In recent years many important changes have occurred in antimicrobial therapy. New antimicrobials are available and a greater database of species-specific pharmacokinetic information is available for antimicrobials used in equine medicine, which allows for more accurate drug dosing. Concerns over drug residues in food animals and the continued development of bacterial resistance has heightened the awareness of rational use of antimicrobials. 186

187

4.2.1

Rational Use of Antimicrobial Agents

One must consider the following questions when developing an antimicrobial regimen:

1. *Does the diagnosis warrant antimicrobial therapy?* Using antimicrobials to treat minor infections or purely viral or inflammatory diseases is irrational and expensive, can be hazardous to the patient, and encourages antimicrobial resistance. Clients have come to expect antimicrobials for trivial infections or just in case an infection may develop. Equine practitioners must resist client pressure to use or prescribe drugs unnecessarily.

2. *What organism(s) are likely to be involved?* For many infections, the likely organism can be predicted successfully from the history and clinical signs.

3. *What is the in vitro antimicrobial susceptibility of the organism?* For many pathogens, the in vitro susceptibility can be predicted reliably. For example, *Streptococcus* species are typically susceptible to penicillin. However, many gram-negative bacteria have unpredictable susceptibilities, and susceptibility testing is essential for determining appropriate drug therapy.

4. *In what part of the body or tissue is the infection located? Will the antimicrobial penetrate to the infection?* Consideration of the pathophysiology of the infection aids in selecting effective therapy. Treating sequestered infections such as mastitis or meningitis requires antimicrobials that readily cross membrane barriers. Antimicrobials characterized by low values for volume of distribution (Vd) are unlikely to reach therapeutic concentrations in such sites.

5. *Will the antimicrobial be effective in the local environment of the organism?* For some antimicrobials the local infection environment reduces their efficacy. Sulfonamides are ineffective in purulent debris, because paraaminobenzoic acid (PABA) released from decaying neutrophils serves as a PABA source for bacteria and reduces the competitive effect of the sulfonamide. Aminoglycosides are ineffective in an abscess because of the acidic, anaerobic environment along with the presence of nucleic acid material from decaying cells that inactivates the aminoglycosides.

6. *What drug formulation and dose regimen will maintain the appropriate antimicrobial concentration for the proper duration of time?* Label doses only apply to label pathogens. When treating off-label, one must adjust the dosage regimen for the antimicrobial susceptibility of the specific pathogen.

7. *What adverse drug reactions or toxicities might be expected? Do the benefits outweigh the risks?* The risks of adverse reactions from antimicrobials often are underappreciated. A serious adverse reaction may complicate treatment of the original problem and even may be fatal. Failure to communicate the risks of adverse drug reactions to clients is a common cause of litigation.

8. *Can one choose an approved product? If using an antimicrobial in an extralabel manner, can one determine appropriate withdrawal times for food animals? Can one determine appropriate withdrawal times for performance horses?* The antimicrobials used in horses are not approved for horses intended for food and lack information on appropriate withdrawal times. Competitive horses are subject to the rules of the association governing the sport regarding drugs, which may vary between organization, state or province, and country. Procaine from procaine penicillin G is one of the most common drugs involved in violations. Understanding the principles of drug elimination allows the practitioner to determine appropriate withdrawal times for competitive or slaughter horses.

4.2.1.1

DOCUMENTING THE INFECTION

One must establish a diagnosis before administering any therapy. Culturing samples from all patients with infectious diseases is not always necessary to identify the organism involved. Often the practitioner can base a diagnosis on clinical experience from similar cases. The signs of some infectious diseases are so obvious that the need for microbiologic identification is minimal; but for those infectious diseases of unknown cause or for those attributable to organisms with irregular antimicrobial susceptibility, no substitute exists for isolation and identification of the causative agent. For these organisms, initial therapy while one waits for culture results must include an antimicrobial with a broad spectrum of activity. However, broad-spectrum drugs are usually more toxic and more expensive than narrow-spectrum drugs. Use of broad-spectrum antimicrobials for trivial infections encourages development of antimicrobial-resistant organisms. Without evidence of a susceptible pathogen, such use is irrational and exposes the patient to unnecessary risks.

Whenever possible, the practitioner should obtain a representative sample of material from the patient. One must beware of sampling grossly contaminated sites such as purulent nasal discharges. One can perform a gram-stain immediately from a direct smear and can direct initial therapy. One should submit samples for appropriate culture and identification. If the identified organism has unpredictable susceptibility patterns, one should request a susceptibility test such as Kirby-Bauer, E test, or minimum inhibitory concentration (MIC) method. In some clinical cases, identification of the pathogen may be made by serologic demonstration of antibodies (e.g., ehrlichiosis, leptospirosis, and brucellosis). 187

4.2.1.2 ANTIMICROBIAL DOSAGE REGIMEN DESIGN

Successful antimicrobial therapy relies on administering sufficient doses so that pathogens at the site of infection are killed or sufficiently suppressed that they can be eliminated by the host immune system. The relationship between the host, bacteria, and drug may be complex. High plasma antimicrobial concentrations are *assumed* to be advantageous in that a large concentration of drug will diffuse into various tissues and body fluids. Drug concentration at the infection site is assumed to be of major importance in determining drug efficacy. Drug movement from plasma to extravascular tissues depends on molecular size, lipid solubility, drug pK_a, local pH, specific cellular transport mechanisms, and degree of protein binding. The relationship between bacteria and drug in the laboratory is described by the following:

Minimum inhibitory concentration: The lowest drug concentration that inhibits bacterial growth.

Minimum bactericidal concentration (MBC): The lowest drug concentration that kills 99.9% of bacteria.

MIC is used to determine drug dose in an attempt to achieve blood and tissue concentrations that exceed the in vitro MIC for the pathogen.

4.2.1.3 INTERPRETING MINIMUM INHIBITORY CONCENTRATIONS

By the National Committee on Clinical Laboratory Standards (NCCLS) definition, MIC values are derived as serially doubling concentrations (in μg/ml).[1] The MIC of a particular pathogen is reported as one of the following numbers:

0.06	0.12	0.25	0.5	1	2	4
8	16	32	64	128	256	512

Susceptible (S), intermediate (I), and resistant (R) designations are derived from break points assigned by the laboratory based on safely achievable *plasma* concentrations and results of clinical trials.[2] When a pathogen is reported as *susceptible*, the recommended dosage of the antimicrobial will reach plasma or tissue concentrations that will inhibit bacterial growth in vivo. When a pathogen is reported as *resistant*, inhibitory antimicrobial concentrations are not safely attainable in the patient. If the pathogen is reported as *intermediate*, then administering the antimicrobial at higher than recommended doses may result in effective therapy.[3] The relationship between drug concentration and microbial inhibition is not a linear predication. As antimicrobial concentration increases in vitro, eventually all bacteria will be inhibited or killed. This fact should not be interpreted to mean that dosage regimens should target these concentrations. Susceptibility testing results predict which bacteria have intrinsic or acquired resistance mechanisms to a particular antimicrobial. In vitro tests do this because bacterial susceptibility usually clusters around a small range of MICs. In Figure 4.2-1 the bacterial inhibition of *Escherichia coli* by amoxicillin has a bimodal distribution. *E. coli* requiring an amoxicillin concentration of 16 μg/ml to be inhibited are likely to have intrinsic or acquired resistance mechanisms, and amoxicillin is unlikely to be a successful treatment for patients with this infection. The large cluster of *E. coli* inhibited by amoxicillin concentrations of 0.5 to 16 μg/ml are considered in the *normal*

range, and 16 μg/ml is considered the break point of susceptibility. As the MIC value increases within the normal range, the probability of successful therapy with amoxicillin decreases; meaning some susceptible *E. coli* are *more* susceptible than others. In vitro susceptibility tests predict treatment outcome fairly well, considering that many variables in the host-pathogen relationship are not taken into account.[2] Antimicrobial susceptibility data may not account for the following[4]:

1. *Host defenses*. The interactions between the host and the pathogen are complex and are not predicted by in vitro tests. Antimicrobial drug action takes place in concert with host defenses such as humoral and cell-mediated immunity, complement components, and nonspecific antibacterial factors such as lactoferrin, lactoperoxidase, and lysozyme.[5]

2. *Drug distribution in the body*. The S, I, and R designations assigned by the microbiology laboratory are based on safely achievable plasma concentrations and do not take into account extremely high concentrations of antimicrobials achieved in organs and fluids of excretion (kidney, urine, and bile) or with local administration of high drug concentrations (e.g., ophthalmic ointments). Pathophysiology may alter drug distribution, and some antimicrobials, such as the tetracyclines, accumulate in pneumonic lung tissues.[6]

3. *Growth rates and size of inoculum*. The incubator of the microbiology laboratory is an ideal world for bacterial growth. Conditions are managed to promote rapid growth, and rapidly dividing bacteria are more susceptible to antimicrobial drugs. Replication rates may be much slower at the infection site, and MICs are generally unreliable for slow-growing bacteria. Standardized inoculums used in the laboratory may over- or underrepresent pathogen numbers in infected tissues.[5]

4. *Mixed infections*. Separate susceptibility testing of pathogens in a mixed infection does not account for the pathologic synergism between bacteria. The by-products of one bacterial infection may facilitate the establishment and growth of another.[7]

188

189

5. *Infection environment*. Many antimicrobials are inactive in purulent exudate, which is typically anaerobic, acidic, and hyperosmolar. Some antimicrobials have different activity in body fluids (plasma, milk, bile) than in nutrient-rich laboratory media. Deposition of fibrin may alter tissue penetration of antimicrobials. Many bacteria are capable of producing a polysaccharide slime capsule to protect them from host factors. Mastitis pathogens typically increase their replication rate when incubated in mastitic milk.[5]

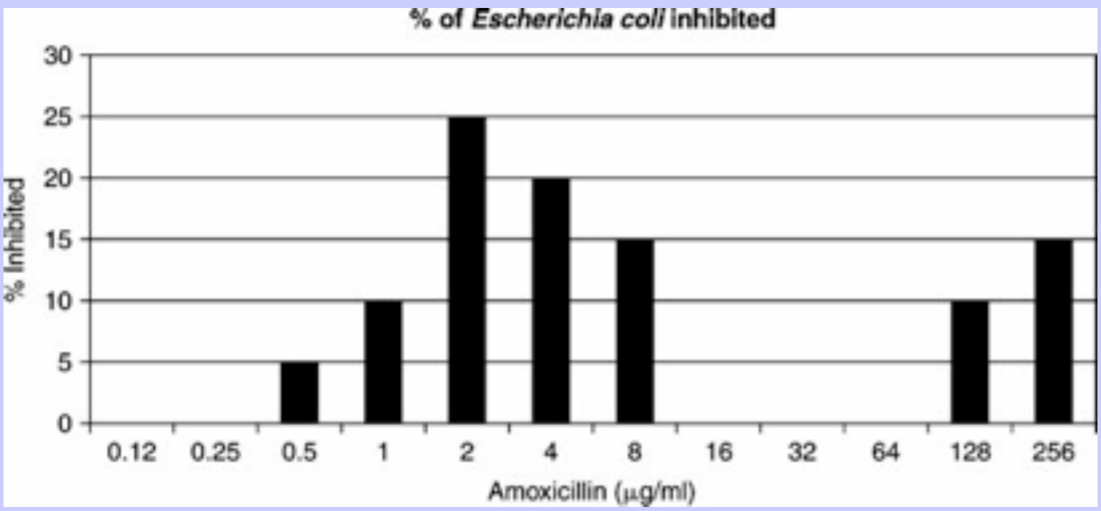
6. *Topically administered antimicrobials are not tested*. Veterinary microbiology laboratories may not do susceptibility testing routinely for antimicrobials that are used only topically. Polymyxin B is one of the most effective antimicrobials for superficial *Pseudomonas* infections,[8] but it causes neurotoxicity and nephrotoxicity if administered systemically and so rarely is included in susceptibility testing. Bacitracin and mupirocin are other examples of topical antimicrobials that rarely are tested in diagnostic laboratories.

7. *In vivo synergism may occur with antimicrobial combinations*. Despite predictions of resistance from susceptibility testing, therapy may be successful because of synergistic combinations of antimicrobials. Synergism between penicillins and aminoglycosides has been recognized for streptococcal, enterococcal, and staphylococcal infections.[9] The synergism is attributed to increased cellular uptake of the aminoglycoside after cell wall damage from the penicillin.

8. *The NCCLS break points may be inappropriate*. The NCCLS break points originally were established with bacterial isolates from human beings, using human pharmacokinetic data and clinical trials in human beings. A veterinary subcommittee was established only in 1993 and only recently has proposed veterinary-specific guidelines for susceptibility tests for some antimicrobials.[10]

Therefore the true relevance of any in vitro MIC in predicting the in vivo results of drug therapy is questionable. The MIC results are not a positive order to use a particular antimicrobial. In selecting the optimal antimicrobial one must take into consideration other factors, such as the site of infection, pharmacokinetics of the drugs, and effect of underlying diseases. Considering all of these factors, drug dosage regimens use a target plasma drug concentration based on some multiple of the in vitro MIC (usually 2 to 10).

Figure 4.2-1 The percentage of *Escherichia coli* inhibited by increasing concentrations of amoxicillin has a bimodal distribution. *E. coli* requiring more than 16 μg/ml of amoxicillin to be inhibited are likely to have intrinsic or acquired resistance mechanisms. Amoxicillin therapy in patients with this pathogen is unlikely to be effective.



4.2.1.4

BACTERICIDAL VERSUS BACTERIOSTATIC ANTIMICROBIALS

Antimicrobials commonly are classified as *bactericidal* or *bacteriostatic* (Box 4.2-1). If the ratio of the MBC to MIC is small (less than 4 to 6), a drug is considered bactericidal and obtaining drug concentrations that kill 99.9% of the organisms exposed is possible. If the ratio of MBC to MIC is large, safely administering dosages of the drug to kill 99.9% of the bacteria may not be possible, and the drug is considered bacteriostatic.[4]

For many drugs the distinction between bactericidal and bacteriostatic is not exact and depends on the drug concentration attained in the target tissue and the pathogen involved. Specific situations in which a

bactericidal drug is preferred over a bacteriostatic drug include immunocompromised patients such as neonates, life-threatening infections such as bacterial endocarditis and meningitis, and surgical prophylaxis. 189

190

4.2.1.4.1 BOX 4.2-1 CLASSIFICATION OF ANTIMICROBIALS

Tetracyclines

4.2.1.5 POSTANTIBIOTIC EFFECT

For some bacterial-antimicrobial interactions, bacterial growth remains suppressed for a period after drug concentration has decreased below the MIC. This postantibiotic effect (PAE) may be the reason that dosage regimens that fail to maintain drug concentration above the MIC are still efficacious. The PAE depends on the antimicrobial and the bacterial pathogen (Table 4.2-1).[11]

4.2.1.6 PHARMACOKINETIC-PHARMACODYNAMIC RELATIONSHIPS

The pharmacokinetic-pharmacodynamic relationship between an antimicrobial and a pathogen determines how one calculates the dosage regimen.[12,13] Antimicrobials are classified broadly as *concentration-dependent* or *time-dependent* for their antibacterial activity (Figures 4.2-2 and 4.2-3; Box 4.2-2).[4] For antimicrobials the efficacy of which is concentration-dependent, high plasma concentration levels relative to the MIC of the pathogen (also known as the inhibitory quotient) and the area under the plasma concentration-time curve that is above the bacterial MIC during the dosage interval (area under the inhibitory curve, or AUIC, which equals AUC/MIC) are the major determinants of clinical efficacy. These drugs also have prolonged PAEs, thereby allowing long dosing intervals with maximum clinical efficacy.[12,13]

TABLE 4.2-1 Length of Postantibiotic Effect for Selected Antimicrobials and Antibiotics

MICROBE	LONG PAE* (>3 HOURS)	INTERMEDIATE PAE	SHORT PAE (<1 HOUR)
Gram positive	Fluoroquinolones	Aminoglycosides	—
	Macrolides	Penicillins	—
	Chloramphenicol	Cephalosporins	—
	Tetracycline	—	—
Gram negative	Fluoroquinolones	—	Penicillins
	Aminoglycosides	—	Cephalosporins
	—	—	Trimethoprim/sulfanomides
Anaerobes	Metronidazole	—	—

* *PAE,* Postantibiotic effect.

For time-dependent antimicrobials, the time during which the antimicrobial concentration exceeds the MIC of the pathogen determines clinical efficacy. The time above the MIC should be at least 50% for most patients and should be closer to 100% for bacteriostatic drugs and for patients that are immunosuppressed. For these drugs, bactericidal activity does not increase with increasing plasma concentrations; once the drug exceeds the MIC of the bacteria, increasing the dosage frequency increases efficacy.[12,13]

4.2.2 Designing the Drug Dosage Regimen

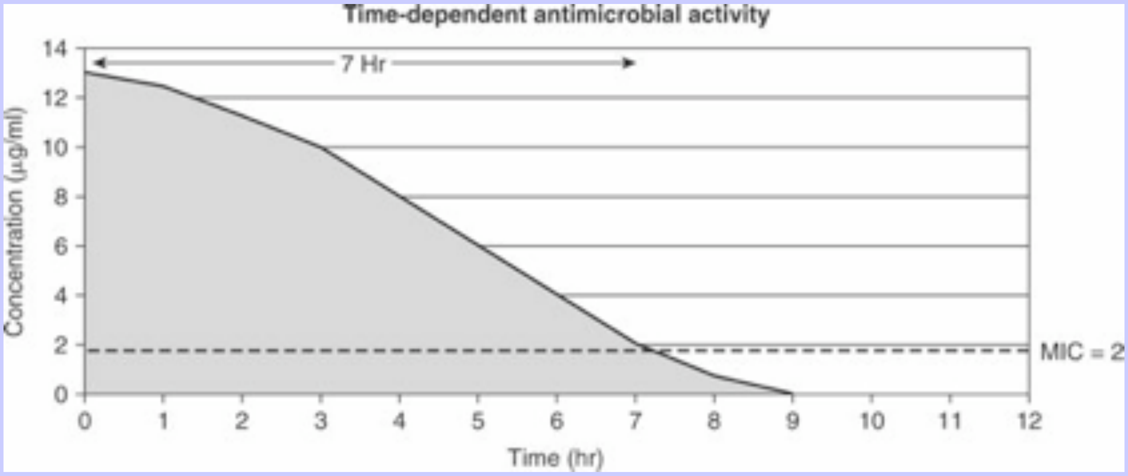
Using the previous information, one designs antimicrobial dosage regimens in one of two ways: to maximize plasma concentrations or to provide a plasma concentration above the bacterial MIC for most of the dosage interval. For concentration-dependent antimicrobials with a prolonged PAE the suggestion for peak plasma drug concentration is eight- to tenfold higher than the MIC of the pathogen.[13] If one knows the Vd of the antimicrobial and assumes once daily dosing, one can calculate a precise drug dosage regimen for the pathogen from the following equation (Box 4.2-3):

$$\text{Dose} = (\text{Vd})(\text{desired plasma concentration})$$

For time-dependent antimicrobials the objective is to keep the average plasma drug concentration above the MIC 190
of the pathogen for the duration of the dosage interval.[13] Using Vd and half-life ($T_{1/2}$) information, one can 191
calculate the dosing regimen from the following equation (Box 4.2-4):

$$\text{Dose} = \frac{(\text{desired average plasma concentration}) \times (\text{Vd})(\text{dosage interval})}{1.44\left(T_{1/2}\right)}$$

Figure 4.2-2 For time-dependent antimicrobials the time during which the antimicrobial concentration exceeds the minimum inhibitory concentration of the pathogen determines clinical efficacy.



4.2.3

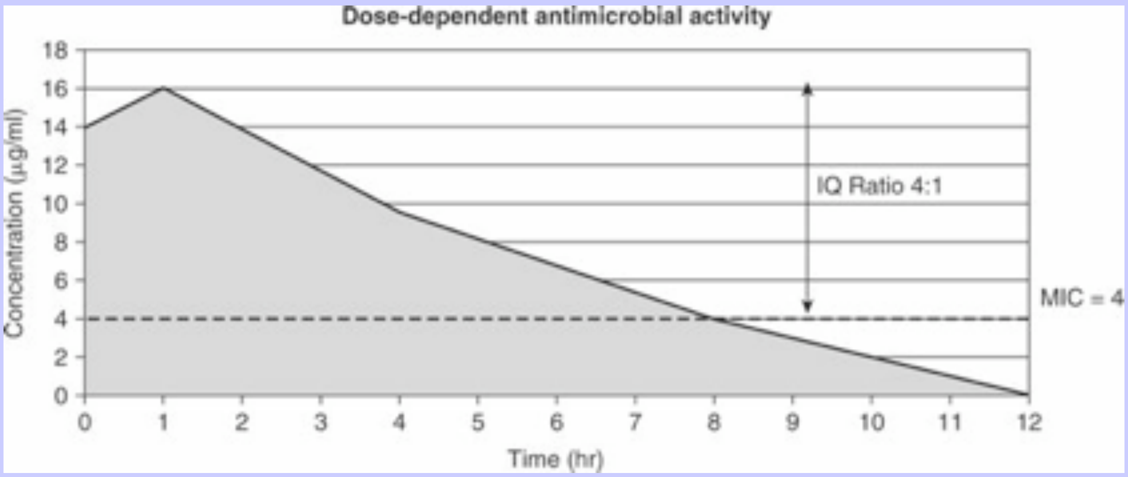
Concurrent Use of Additional Antimicrobials

Combination antimicrobial therapy is commonplace in veterinary medicine, but combination therapy rarely has been demonstrated as superior to single-drug therapy through clinical trials. Use of multiple antimicrobial drugs should be limited to the following situations:

1. Known synergism against specific organisms[9]
2. Prevention of rapid development of bacterial resistance[14]
3. Extension of antimicrobial spectrum in initial therapy of life-threatening conditions
4. Treatment of known mixed bacterial infections[15]

Multiple antimicrobial therapy is implicated as a cause of diarrhea in horses, likely from the additive antibacterial effects against normal gastrointestinal flora.[16] One should avoid antagonistic combinations such as penicillin and tetracyclines; penicillins require actively dividing bacteria to exert their bactericidal effects on the bacterial cell wall, whereas the bacteriostatic action of tetracyclines suppresses cell wall formation.[4]

Figure 4.2-3 For concentration-dependent antimicrobials, the inhibitory quotient *(IQ)* and the area under the inhibitory curve are the major determinants of clinical efficacy.



4.2.4

Prophylactic Use of Antimicrobials

Few reports have examined the efficacy of prophylactic antimicrobial use in veterinary medicine in general and 191
in horses specifically.[17] Because of the lack of controlled veterinary studies, information on prophylaxis is 192
extrapolated mostly from human studies. The risk of infection must warrant the use of prophylactic antimicrobials. The risks of adverse effects from the prophylactic drug administration must be less than the risk of developing disease and its consequences. In veterinary medicine, most of the risk of infection depends on the skill of the surgeon and handling practices in the hospital.[18] One should know or accurately predict the organism(s) likely to cause the infection and the antimicrobial susceptibility. The antimicrobial should be bactericidal and must be administered and must diffuse to the site of potential infection before the onset of infection. One should consider drugs that can be given intravenously and have a high Vd. Drugs used prophylactically should not be those that would be used therapeutically. The duration of antimicrobial prophylaxis should be as abbreviated as possible. Most of the time, a single preoperative dose is sufficient and cost-effective.[19]

4.2.4.1

BOX 4.2-2 CLASSIFICATION OF ANTIMICROBIALS BASED ON MEANS OF EFFECT

Tetracyclines

4.2.4.2

BOX 4.2-3 DOSAGE REGIMEN FOR A CONCENTRATION-DEPENDENT ANTIMICROBIAL

You are treating a valuable neonatal foal with a *Klebsiella pneumoniae* infection with gentamicin. The minimum inhibitory concentration of gentamicin for *Klebsiella* is 2 μg/ml. The desired plasma concentration is 10 times the minimum inhibitory concentration at 20 μg/ml. The volume of distribution of gentamicin in the foal is 0.3 L/kg. The dose calculated is as follows:

$$\begin{aligned}\text{Dose} &= (300\ \text{ml/kg})(0.02\ \text{mg/ml})\\ &= 6\ \text{mg/kg}\end{aligned}$$

4.2.4.3

BOX 4.2-4 DOSAGE REGIMEN FOR A TIME-DEPENDENT ANTIMICROBIAL

You want to treat a foal with *Rhodococcus equi* pneumonia with erythromycin. The minimum inhibitory concentration for *R. equi* is 0.25 μg/ml. In foals the volume of distribution is 4 L/kg, and the elimination half-life 1 hour. You pick a dosage interval of 6 hours and an average desired plasma concentration of 10 times the minimum inhibitory concentration because *R. equi* is an abscess-forming, intracellular pathogen.

$$\text{Dose} = \frac{(\text{desired avg. plasma concn.})(\text{Vd})(\text{dosage interval})}{1.44\left(T_{1/2}\right)}$$

$$\text{Dose} = \frac{(0.0025\ \text{mg/ml})(400\ \text{ml/kg})(6\ \text{hours})}{1.44\ (1\ \text{hour})}$$

$$\text{Dose} = 4.2\ \text{mg/kg}$$

This agrees with published recommendations of 3 to 5 mg/kg for intravenously administered erythromycin for treating *R. equi*. Because of the poor bioavailability of the oral formulations, the dosage is increased 5 times for an oral dosage of 25 mg/kg every 6 hours.

4.2.5 β-Lactams: Penicillins and Cephalosporins

The β-lactam antibiotics are among the most commonly used antibiotics. Their use and popularity is due to their safety, efficacy, flexibility in dosage forms, and low expense. Penicillins and cephalosporins have a four-member β-lactam ring that is unstable and is a major target for bacterial resistance mechanisms.

4.2.5.1 MECHANISM OF ACTION

β-Lactam antibiotics act on enzymes called *penicillin-binding proteins (PBP)* responsible for building the bacterial cell wall.[20] Therefore they are only active against rapidly multiplying organisms when the binding of penicillin within the cell wall interferes with production of cell wall peptidoglycans and results in cell lysis in a hypo- or isoosmotic environment. Anywhere from two to eight PBPs may be in a bacterium. When β-lactam 192
antibiotics bind covalently and irreversibly to the PBPs, they disrupt the bacterial cell wall and lysis occurs. 193
Differences in the spectrum and action of β-lactam antibiotics are due to their relative affinity for different PBPs. To bind to the PBPs, the β-lactam antibiotic first must diffuse through the bacterial cell wall. Gram-negative organisms have an additional lipopolysaccharide layer that decreases antibiotic penetration. Therefore gram-positive bacteria are usually more susceptible to the action of β-lactams than gram-negative bacteria.[21] The penicillins penetrate mammalian cells poorly and so have little use in treating intracellular pathogens.

4.2.5.2 MECHANISMS OF RESISTANCE

Resistance mechanisms to the β-lactams include failure of the antibiotic to penetrate the outer bacterial cell layers and alteration of PBPs that decrease the affinity of the PBP for the antibiotic.[22] This resistance mechanism occurs with methicillin-resistant staphyloccoci. A third mechanism of resistance is from production of β-lactamase enzymes.[23] Bacteria produce as many as 50 β-lactamase enzymes (penicillinases, cephalosporinases).[24] These enzymes hydrolyze the cyclic amide bond of the β-lactam ring and inactivate the antibiotic. Coagulase-positive *Staphylococcus* spp. produce staphylococcal β-lactamases. The synthesis of these enzymes is plasmid-encoded, and the enzymes are exocellular. These enzymes typically do not inactivate cephalosporins and antistaphylococcal penicillins. Most of these β-lactamases can be inactivated by inhibitors such as clavulanic acid and sulbactam. The gram-negative β-lactamases are a diverse group of enzymes that may be encoded on chromosomes or phasmids.[24] *E. coli* lactamase is plasmid derived and hydrolyzes cephalosporins and penicillins. Chromosomal-mediated lactamases hydrolyze penicillin or cephalosporins or both.[23]

4.2.6 Benzylpenicillin (Penicillin G)

Penicillin G was the first antibiotic developed and remains one of the most effective antibiotics available. Penicillin G is still the initial drug of choice for many bacterial infections.

4.2.6.1 SPECTRUM OF ACTIVITY

Aerobic bacteria susceptible to penicillin G include most β-hemolytic streptococci, β-lactamase–negative staphylococci, *Actinomyces* species, some *Bacillus anthracis, Corynebacterium* spp., and *Erysipelothrix*

rhusiopathiae.[25] Most species of anaerobes are susceptible, excluding β-lactamase-producing *Bacteroides* spp.[26,27] Penicillin G is inactivated easily by β-lactamases and has little efficacy against organisms that can produce these enzymes. In addition, penicillin G is ineffective against those bacteria that are resistant by other mechanisms, such as having a relatively impermeable cell wall. Therefore penicillin G has little activity against many staphylococci and most gram-negative bacteria.[25]

4.2.6.2 PHARMACOKINETICS

4.2.6.2.1 Absorption

Penicillin is a weak acid with a pK_a of 2.7; therefore it is highly ionized in plasma. Gastric absorption of penicillin G is poor because it hydrolyzes rapidly in the acidic environment of the stomach. Phenoxymethyl penicillin (penicillin V) can be given orally to horses and has a $T_{½}$ of absorption of 0.2 hours.[28] The sodium and potassium salts of penicillin G are the only dosage forms that are suitable for intravenous administration, and they are absorbed quickly from intramuscular or subcutaneous sites of administration. Procaine penicillin G is absorbed more slowly from intramuscular administration than the sodium or potassium salts and so produces lower but more sustained plasma concentrations. Benzathine penicillin G is the least soluble of the dosage forms and is absorbed slowly, producing sustained but subtherapeutic plasma concentrations of penicillin G.[29] The rate of absorption from intramuscular injections of procaine penicillin G varies depending on the injection site, with injections into the neck muscle producing more rapid absorption and higher plasma concentrations than with injections into the hindquarters.[30]

4.2.6.2.2 Distribution

The Vd of sodium penicillin G is 0.7 L/kg,[31] and a moderate degree of protein binding occurs (52% to 54%).[32] After absorption, penicillin diffuses mainly in extracellular fluid and may not reach therapeutic concentrations in sequestered infections.[33]

4.2.6.2.3 Elimination

Elimination of penicillin is primarily renal, as unchanged drug, by glomerular filtration and active renal tubular secretion. The elimination $T_{½}$ of penicillin G is 1 hour,[32,33] and total clearance is 8.5 ± 1.33 ml/min/kg.[31] Orally administered penicillin V has an elimination $T_{½}$ of 3.7 hours.[28]

4.2.6.3 ADVERSE EFFECTS AND DRUG INTERACTIONS

4.2.6.3.1 Immune-Mediated Reactions

Penicillin is associated with autoimmune hemolytic anemia (type II hypersensitivity),[34,35] and anaphylaxis (type I hypersensitivity) in horses.[36] The immune-mediated anemia usually resolves with discontinuation of penicillin therapy. Anaphylaxis usually occurs after previous exposure to penicillin and can be fatal. Intravenously administered epinephrine, oxygen administration, and respiratory support are indicated.

Although penicillin and cephalosporins are assumed widely to be cross-reactive in sensitive individuals, the actual incidence in human beings is low.[37] 193

194

4.2.6.3.2

Procaine Reactions and Use in Performance Horses

When procaine penicillin G products are administered accidentally intravascularly, they cause extreme central nervous system (CNS) stimulation.[38,39] Most horses survive unless they fatally traumatize themselves during the reaction. Diazepam attenuates the reaction if given before the procaine but has no effect if given after procaine administration. Veterinary formulations contain higher concentrations of procaine than human formulations, and high temperatures increase the solubility of procaine. Therefore procaine penicillin G should be refrigerated and administered by careful intramuscular injection.[39] Procaine is eliminated slowly and commonly causes violative residues in racehorses and performance horses.[38]

4.2.6.3.3

Electrolyte Imbalances

The sodium or potassium content of intravenous formulations of penicillin G can contribute to electrolyte imbalances associated with congestive heart failure and renal function impairment. A million units of potassium penicillin contains 1.7 mEq of potassium and so should be administered by slow intravenous injection.

4.2.6.3.4

Phenylbutazone

Concurrent administration of phenylbutazone in horses increases plasma concentrations of penicillin G but lowers tissue concentrations. The effect is likely caused by a lower peripheral distribution.[31]

4.2.6.4

FORMULATIONS

Sodium and potassium penicillin (also called crystalline penicillin) are water-soluble formulations and may be injected intravenously, intramuscularly, or subcutaneously. They achieve rapid plasma concentrations but have short elimination half-lives and so must be administered frequently. Potassium penicillin is usually less expensive than sodium penicillin but must be administered more carefully, because rapid intravenous administration can cause cardiac arrhythmias. Procaine penicillin G is a poorly soluble salt that is absorbed slowly following intramuscular or subcutaneous injection. Procaine is the most commonly used formulation of penicillin. Benzathine penicillin G is an insoluble salt used in long-acting penicillin preparations that contain a 50:50 mixture of procaine penicillin G and benzathine penicillin G.

4.2.6.5

CLINICAL USE

Penicillin is still the antimicrobial of choice for many diseases in equine practice such as streptococcal and anaerobic infections. The intravenous formulations are used when high doses are necessary to get adequate concentrations at the site of infection in life-threatening situations. The dosage of penicillin G varies greatly depending on the formulation, species, and disease being treated. Penicillin often is used irrationally to treat traumatic wounds infected with staphylococci, because most equine isolates are β-lactamase–producing *Staphylococcus aureus*.[40]

4.2.7 Aminopenicillins

4.2.7.1 SPECTRUM OF ACTIVITY

The aminopenicillins are able to penetrate the outer layer of gram-negative bacteria better than penicillin G; therefore they have activity against many of the gram-negative bacteria (*Escherichia coli, Salmonella*, and *Pasteurella* spp.) and gram-positive bacteria. However, gram-negative bacteria easily acquire resistance to the aminopenicillins, so the antibiotics are not usually effective against *Klebsiella, Proteus, Pseudomonas*, and *Staphylococcus aureus*. Most anaerobes are sensitive, except β-lactamase–producing strains of *Bacteroides*.[41] Amoxicillin penetrates the gram-negative cell more easily than does ampicillin; therefore it has greater activity against gram-negative bacteria.[25]

4.2.7.2 PHARMACOKINETICS

4.2.7.2.1 Absorption

In horses, ampicillin sodium is absorbed well following intramuscular or subcutaneous administration; however, adult horses absorb oral dosage forms poorly.[42] Intramuscularly administered ampicillin trihydrate produces lower ampicillin blood concentrations that extend over a longer period than does intramuscularly administered ampicillin sodium.[43] Oral absorption of amoxicillin is between 5.3% and 10.4% in adult horses,[44,45] but 36% to 42% in foals.[46] The ampicillin prodrugs are converted to ampicillin as they are absorbed from the gastrointestinal tract. Compared with the bioavailability of oral ampicillin (2%), the ampicillin esters have improved oral bioavailabilities in adult horses: pivampicillin (31%), bacampicillin (39%), and talampicillin (23%).[47] The low oral bioavailability of ampicillin esters is caused by chemical hydrolysis in the high pH of equine ileal contents.

4.2.7.2.2 Distribution

The aminopenicillins diffuse rapidly and widely into most body fluids; distribution into cerebrospinal fluid (CSF) is low unless the meninges are inflamed.[41] Penetration into synovial fluid is high.[42,45,48,49] The Vd of amoxicillin is 0.19 in adult horses[45] and 0.27 L/kg in neonatal foals.[46] The Vd of ampicillin in horses is 0.18 L/kg.[43] Peak serum concentrations of ampicillin are 6.2 to 9.7 mg/ml 16 minutes after an intramuscular dose of 10 mg/kg of ampicillin sodium.[42] In subcutaneous tissue chambers in ponies, concentrations of ampicillin sodium (intravenous), pivampicillin (oral), and procaine penicillin G (intramuscular) remained 194
above the MIC of *Streptococcus zooepidemicus* for 8, 12, and 24 hours, respectively.[50] The protein binding 195
of amoxicillin is moderate (37% to 38%),[51] whereas protein binding is low for ampicillin (6% to 8%).[32]

4.2.7.2.3 Elimination

Amoxicillin and ampicillin are excreted unchanged primarily in the urine. Ten percent to 25% of the administered dose of amoxicillin is excreted in the form of penicilloic acid.[41] The elimination $T_{1/2}$ of

amoxicillin is approximately 1 hour in horses and foals.[44,46,51] The elimination $T_{½}$ of ampicillin ranges from 0.5 hour to 1.5 hours.[42,43,48,52]

4.2.7.3 ADVERSE EFFECTS AND DRUG INTERACTIONS

Amoxicillin and ampicillin have the same adverse effects as penicillin G. A beneficial interaction is their synergism when combined with β-lactamase inhibitors such as clavulanic acid and sulbactam.

4.2.7.4 FORMULATIONS

Sodium ampicillin is available as an aqueous formulation for intravenous, intramuscular, and subcutaneous injection. The reconstituted aqueous formulations are unstable after more than a few hours. Ampicillin trihydrate is a poorly soluble, slow-release aqueous suspension; absorption is erratic and the drug produces prolonged but low plasma concentrations. Ampicillin trihydrate is approved for use in large animals.

4.2.7.5 CLINICAL USE

Indications for ampicillin or amoxicillin are few, because they offer little advantage over benzylpenicillins because of acquired resistance in gram-negative bacteria. Sodium ampicillin may be substituted for sodium or potassium penicillin as a choice for surgical prophylaxis.

4.2.8 Antipseudomonal Penicillins

4.2.8.1 SPECTRUM OF ACTIVITY

Carbenicillin, ticarcillin, and piperacillin are the antipseudomonal penicillins. This group of penicillins can penetrate the outer cell wall of *Pseudomonas* spp. and other gram-negative bacteria. They are susceptible to β-lactamase inactivation by *Klebsiella*. This group has activity against gram-negative bacteria at the expense of activity against gram-positive bacteria. They retain activity against anaerobic bacteria and are synergistic when administered with aminoglycosides.[41] Ticarcillin has been administered systemically to horses.[53,54]

4.2.8.2 PHARMACOKINETICS

Absorption of intramuscularly administered ticarcillin is 65%, and the elimination $T_{½}$ is less than 1 hour in horses.[53,54] Peak endometrial concentrations after intravenous administration are 12.9 μg/g but are greater than 150 μg/g when 6 g of ticarcillin is diluted in 250 ml of saline and infused into the uterus.[54]

4.2.9 β-Lactamase Inhibitors

4.2.9.1 SPECTRUM OF ACTIVITY

The β-lactamase inhibitors are a specific class of drugs with little antibacterial action of their own, but they inhibit bacterial β-lactamase. β-lactamase inhibitors only assist in the destruction of bacteria that produce β-lactamase enzymes; other forms of resistance, such as alteration of penicillin-binding proteins, are not

affected. β-lactamase inhibitors are always combined with β-lactam antibiotics. The primary drugs of this class are clavulanic acid and sulbactam. They extend the spectrum of amoxicillin and ampicillin to include β-lactamase producing *E. coli, Klebsiella, Proteus*, and *Staphylococcus*. Most anaerobes, including *Bacteroides fragilis*, are susceptible. These drugs combine with the β-lactamase that is produced by gram-negative and some gram-positive bacteria. An inactive enzyme complex forms, and the co-administered antibiotic then is able to exert its effect.[41] Ampicillin-sulbactam[55,56] and ticarcillin–clavulanic acid have been used in foals.[57,58]

4.2.9.2 PHARMACOKINETICS

4.2.9.2.1 Absorption

Absorption of ticarcillin and clavulanic acid in foals depends on age, for neonatal foals have a higher systemic bioavailability than older foals (100% and 88% versus 54% and 68%, respectively).[58] When administered intramuscularly with clavulanic acid, ticarcillin demonstrates flip-flop kinetics in which the elimination half-life is longer after intramuscular than intravenous injection because of slow absorption from the injection site.[57]

4.2.9.2.2 Distribution

The Vd of ticarcillin in older foals was 0.24 L/kg, and the Vd of clavulanic acid was 0.48 L/kg.[57] In neonatal foals the Vd of ticarcillin was higher at 0.69 L/kg, as would be expected for a low-Vd drug in a neonate with its increased extracellular fluid volume.[58]

4.2.9.2.3 Elimination

Ticarcillin demonstrates age-dependent elimination in foals. In neonatal foals the Vd and clearance of ticarcillin were approximately double those reported for older foals and mares.[58] The renal elimination mechanism of ticarcillin appears immature in a 3-day-old foal but is near normal adult function by 28 days of age.

4.2.9.3 ADVERSE EFFECTS AND DRUG INTERACTIONS

When administered intramuscularly into the hindquarters at a concentration of 400 mg/ml ticarcillin plus 13.2 195
mg/ml clavulanic acid, foals showed signs of significant local discomfort.[57] A lower concentration of drug did 196
not cause signs of discomfort in neonatal foals.[58]

The penicillin–β-lactam inhibitor drugs can be used with aminoglycosides for a synergistic effect against the pathogens commonly encountered in septicemic foals.

4.2.9.4 FORMULATIONS

Amoxicillin–clavulanic acid is only available as oral tablets or suspension for human beings and small animals. Ampicillin-sulbactam is available as a trihydrate formulation labeled for cattle in Canada. Sodium

ampicillin-sulbactam and ticarcillin disodium–clavulanic acid formulations are available for human use in the United States.

4.2.9.5 CLINICAL USE

The ampicillin–sulbactam trihydrate formulation frequently is used in horses in Canada as a treatment option for respiratory infections.[55,56] Ticarcillin–clavulanic acid is a treatment option for gram-negative bacterial infections in valuable foals.

4.2.10 Cephalosporins

In 1945 a fungus, *Cephalosporium acremonium*, was isolated from a seawater sample near a sewage outlet in Sardinia. The fungus was found to produce an antibiotic compound that inhibited the growth of many gram-positive and gram-negative bacteria. In addition, the compound resisted the action of staphylococcal β-lactamases. This resistance to β-lactamases and the widespread emergence of penicillin-resistant staphylococci in the 1950s provided the impetus for the development of the cephalosporin antibiotics.

4.2.10.1 SPECTRUM OF ACTIVITY

In human medicine, cephalosporins are used widely; however, cephalosporins are said to be drugs in search of diseases to treat, meaning that precise therapeutic indications for these drugs are difficult to define and a tendency exists to use these drugs when older or cheaper drugs would suffice.[59] The use of cephalosporins in equine medicine is not so widespread because of their expense and the fact that equine clinical experience includes only a few specific agents. Cephalosporins usually are grouped into three generations based primarily on their antibacterial activity, but some of the newer cephalosporins do not easily fit into this scheme.[20]

First-generation cephalosporins are effective against most gram-positive cocci, including β-lactamase–producing staphylococci, by virtue of higher affinity for the PBPs. They also have greater activity against members of the Enterobacteriaceae than other β-lactam antibiotics but may be degraded by β-lactamases (except staphylococcal β-lactamase), which makes them ineffective against some gram-negative bacteria.[21] The first-generation cephalosporins are active against staphylococci and streptococci with the exception of the methicillin-resistant staphylococci. Although most corynebacteria are susceptible, *Corynebacterium* (now *Rhodococcus*) *equi* is usually resistant.[20] Among the commonly encountered gram-negative bacteria, *E. coli, Klebsiella, Haemophilus, Proteus, Actinobacillus, Pasteurella*, and *Salmonella* species are regularly susceptible to first-generation cephalosporins. Indole-positive *Proteus, Enterobacter, Serratia*, and *Pseudomonas* species are resistant. Most anaerobic bacteria are susceptible, except β-lactamase–producing *Bacteroides*.[59] None of the first-generation cephalosporins is approved for use in horses, but cefazolin,[60] cefadroxil,[61,62] cephalothin,[63] cephapirin,[64,65] and cephradine[66] have been used in horses.

Second-generation cephalosporins in general have greater activity against gram-negative bacteria that are resistant to the first-generation cephalosporins (e.g., *Escherichia coli, Klebsiella, Proteus*, and *Enterobacter*) but are no more active against the gram-positive bacteria than the first-generation drugs.[20] The increased activity of these cephalosporins is caused by increased resistance to gram-negative β-lactamases.[21] Cefoxitin has been used in mares.[67]

Third-generation cephalosporins have increased activity against gram-negative bacteria because of their resistance to β-lactamases, and most achieve therapeutic concentrations in the CNS.[20] In the past, these cephalosporins were considered to be unreliable and erratic against gram-positive organisms. However, recent evidence indicates they actually have good activity against gram-positive organisms, except for enterococci and *Listeria*.[59] Some of the third-generation products have good activity against *Pseudomonas* spp.[21] Cefoperazone, cefotaxime, and ceftriaxone have been investigated in horses,[68–70] and cefotaxime has been used successfully to treat septicemia and meningitis in neonatal foals.[71]

Fourth-generation cephalosporins have broad-spectrum activity against gram-positive and gram-negative bacteria by increased resistance to β-lactamases. Cefepime is active against many gram-negative bacteria that are resistant to third-generation cephalosporins and has antipseudomonal activity similar to ceftazidime. However, cefepime lacks activity against methicillin-resistant staphylococci and enterococci and has variable activity against anaerobes.[59] Cefepime has been evaluated in neonatal foals and adult horses.[72,73]

Ceftiofur is marketed as a *new*-generation cephalosporin because it does not fall clearly into the previous classification scheme. Ceftiofur is active against respiratory pathogens such as streptococci, *Pasteurella* spp., 196
and *Haemophilus* spp. and most anaerobes but has less activity against *Staphylococcus aureus* and 197
Enterobacteriaceae.[74] *Bacteroides* spp. and *Pseudomonas* spp. are resistant.[75] Ceftiofur is approved only in horses for treating respiratory tract infections caused by *Streptococcus zooepidemicus*. When administered, ceftiofur is metabolized rapidly to the active metabolite desfuroylceftiofur.[76] Desfuroylceftiofur is less active than ceftiofur against *Staphylococcus aureus* and *Proteus* spp.[77] Diagnostic laboratories use a ceftiofur disk for susceptibility testing because of the instability of desfuroylceftiofur, so susceptibility testing results for staphylococci and *Proteus* sp. may not be reliable for predicting the efficacy of ceftiofur therapy.

4.2.10.2 PHARMACOKINETICS

4.2.10.2.1 Absorption, Distribution, and Elimination

Table 4.2-2 gives the pharmacokinetic parameters for the cephalosporins in horses. Intramuscular and subcutaneous administration of cephalosporins results in rapid drug absorption, but the extent varies with the drug and the species. Oral bioavailability is acceptable in neonates but rapidly becomes too low to be practical for older foals or adults.[61,62] The values for Vd in horses for the cephalosporins are typically low (<0.3 L/kg), indicating distribution primarily to extracellular fluid, and indeed have good distribution into the extracellular fluid of most tissues, including pleural, pericardial, and synovial fluid.[21] Penetration into cortical and cancellous bone is usually adequate.[20] Cephalosporins penetrate poorly into the ocular humor and, except for some third-generation drugs, do not achieve therapeutic concentrations in the CNS.[21] In general the third-generation cephalosporins have an increased ability to penetrate the CNS.[59] Higher Vd values for foals reflect the increased extracellular fluid compartment of the neonate.[61,78] Most cephalosporins are eliminated rapidly as unchanged drug in the urine. The liver deacetylates cephalothin, cephapirin, cefotaxime, and ceftiofur.[20] Their metabolites have significant antibacterial activity. For ceftiofur, most of the antibacterial activity is attributed to its metabolite, desfuroylceftiofur.[76] Renal excretion of cephalosporins occurs through a combination of glomerular filtration and active tubular secretion. Therefore the dosage regimen for most cephalosporins must be modified for patients in renal

failure.[20] For the cephalosporins that undergo hepatic metabolism, hepatic insufficiency may result in decreased metabolism and increased drug accumulation.[20] Dose-dependent kinetics occurred in foals
administered cefadroxil, as evidenced by increasing mean residence time, suggesting saturation of immature 197
renal tubular secretion at high doses.[61] For some cephalosporins, delayed absorption from the intramuscular 198
injection site results in flip-flop kinetics.[68]

TABLE 4.2-2 Pharmacokinetics of Cephalosporins in Horses

DRUG	VOLUME OF DISTRIBUTION (L/kg)	HALF-LIFE OR MRT[*] (HOUR)	PROTEIN BINDING (%)	CLEARANCE (ml/min/kg)	BIOAVAILABILITY (%)	DOSE[†] (mg/kg)

4.2.10.2.2

Adverse Effects and Drug Interactions

The adverse effects of the cephalosporins are similar to those reported for the penicillins. In general, cephalosporins have a high therapeutic index. Bleeding disorders are reported in human beings but have not been reported in animals.[20] The reaction appears to be related to vitamin K antagonism.[20] Ceftriaxone and cefepime cause gastrointestinal disturbances after administration to foals and horses.[69,72,73] Ceftiofur is associated with injection site inflammation and diarrhea from altered gastrointestinal flora in horses.[79–81] The currently available cephalosporins are considered to be potentially nephrotoxic via deposition of immune complexes in the glomerular basement membrane or from a direct toxic effect leading to acute tubular necrosis.[20] In human medicine, cephalosporins are recommended not to be used with aminoglycosides; however, animal studies demonstrate a protective effect of the cephalosporins against nephrotoxicity.[20] Like the penicillins, cephalosporins can be synergistic with aminoglycosides.

4.2.10.3

FORMULATIONS

Cefadroxil is available as veterinary formulated tablets or suspension for small animals. The parenteral formulations of cephalosporins are usually sodium salts. Cefepime is available as a hydrochloride formulation.

4.2.10.4

CLINICAL USE

Ceftiofur is the only cephalosporin routinely used in equine practice and is a good alternative to penicillin or trimethoprim/sulfonamides for treating streptococcal infections. First-generation cephalosporins are an effective alternative to penicillins in treating staphylococcal and streptococcal infections. All of the first-generation cephalosporins have essentially the same spectrum of activity, so the choice of an individual drug is based on pharmacokinetic and economic factors. No second-generation cephalosporins are approved for use in veterinary medicine. Because the cost of these drugs is roughly twice that of the first-generation cephalosporins, their use should be limited to situations in which the infection is resistant to a first-generation drug and susceptible to a second-generation drug and the only other therapy options are unacceptably toxic. The third- and fourth-generation cephalosporins usually are restricted to patients with bacterial infections caused by strains with multiple-drug resistance. All of the third- and fourth-generation cephalosporins are expensive and are used rarely in equine practice. These drugs are most likely to be useful in valuable patients with nosocomial pneumonia, postoperative wound infections, and urinary tract infections related to catheterization and in patients with reduced renal function so that aminoglycosides are contraindicated.

4.2.11

Aminoglycosides

The aminoglycoside antibiotics include *streptomycin, neomycin, gentamicin, amikacin, tobramycin*, and *kanamycin*. They have a chemical structure of amino sugars joined by a glycoside linkage. This group is important in veterinary medicine for treating gram-negative infections caused by enteric pathogens such as *Escherichia coli*.[82] Gentamicin and amikacin are the most commonly used aminoglycosides in horses. Tobramycin is related structurally to kanamycin and has 4 times the activity of gentamicin against *Pseudomonas* spp. Because of the expense, kanamycin use in horses usually is limited to treating melting corneal ulcers caused

by gentamicin-resistant *Pseudomonas*. Streptomycin is no longer available for use, and neomycin is administered only topically because of systemic toxicity.

4.2.11.1
MECHANISM OF ACTION

The aminoglycosides are large molecules with numerous amino acid groups, making them basic polycations that are highly ionized at physiologic pHs. Aminoglycosides must penetrate the bacteria to assert their effect. Susceptible, aerobic gram-negative bacteria actively pump the aminoglycoside into the cell, an action initiated by an oxygen-dependent interaction between the antibiotic cations and the negatively charged ions of the bacterial membrane lipopolysaccharides. This interaction displaces divalent cations (Ca^{2+}, Mg^{2+}), which affects membrane permeability. Inside the bacterial cell, aminoglycosides bind to the 30-S ribosomal subunit and cause a misreading of the genetic code, interrupting normal bacterial protein synthesis. The interruption leads to changes in the cell membrane permeability, additional antibiotic uptake, further cell disruption, and ultimately cell death.[83]

Aminoglycoside action is bactericidal and dose (concentration) dependent. For example, concentrations of gentamicin in the range of 0.5 to 5.0 μg/ml are bactericidal for gram-positive and some gram-negative bacteria. At 10 to 15 μg/ml, gentamicin is effective against the more resistant bacteria such as *Pseudomonas aeruginosa, Klebsiella pneumoniae*, and *Proteus mirabilis*. The clinical implication is that high initial doses of aminoglycosides increase ionic bonding, enhancing the initial concentration-dependent phase of rapid antibiotic internalization, leading to greater immediate bactericidal activity. Human clinical studies demonstrate that proper initial therapeutic doses of aminoglycosides are critical in reducing mortality from gram-negative septicemia.[84]

The aminoglycosides have a significant *postantibiotic effect*, the time in which antimicrobial concentrations 198
are below the bacterial MIC, but the antimicrobial-damaged bacteria are more susceptible to host defenses. 199
The duration of the PAE tends to increase as the initial aminoglycoside concentration increases.[84]

An alkaline environment (pH 6 to 8) enhances antimicrobial activity of aminoglycosides. They bind to and are inactivated by the nucleic acid material released by decaying white blood cells. Therefore they are usually ineffective in the acidic, hyperosmolar, anaerobic environment of abscesses.[82]

4.2.11.2
SPECTRUM OF ACTIVITY

The aminoglycosides are effective against most gram-negative bacteria, including *Pseudomonas*. They are somewhat effective against staphylococci, although resistance can occur. They are often effective against enterococci, but therapy against streptococci is more effective when combined with a β-lactam antibiotic. *Salmonella* and *Brucella* spp. are intracellular pathogens and are often resistant. Aminoglycosides are ineffective against anaerobic bacteria because aminoglycoside penetration into the bacteria requires an oxygen-dependent transport mechanism. Gentamicin and amikacin are the most commonly used aminoglycosides in horses. Gentamicin has been used widely for treating gram-negative organisms and some gram-positive organisms in horses. Its use is limited primarily by risk of toxicity. Amikacin was developed from kanamycin and has the broadest spectrum of activity of the aminoglycosides. Amikacin is effective against strains not susceptible to other aminoglycosides because it is more resistant to bacterial enzymatic inactivation and is considered the least nephrotoxic.[82]

4.2.11.3

MECHANISMS OF RESISTANCE

Aminoglycoside resistance is caused primarily by enzymes encoded by genes located on bacterial plasmids.[82] These phosphotransferases, acetyltransferases, and adenylyltransferases act internally to alter the aminoglycoside and prevent it from binding to ribosomes. Amikacin is least susceptible to enzyme inactivation. Plasmid-mediated resistance to the aminoglycosides is transferable between bacteria. A single type of plasmid may confer cross-resistance to multiple aminoglycosides and to other unrelated antimicrobials. A single bacterial isolate may have any one of a variety of combinations of resistance to different antibiotics conferred by the particular plasmid it carries. As an example, an *E. coli* strain may be resistant to ampicillin, apramycin, chloramphenicol, gentamicin, kanamycin, sulfonamide, streptomycin, tetracycline, and trimethoprim.[85] The nature of resistance in organisms such as *E. coli* and *Salmonella* species has been a focus of international research because of concerns about potential transference of antimicrobial resistance from animal to human pathogens.[86] Bacteria also may use other methods of reducing the efficacy of aminoglycosides. Some strains of bacteria are less permeable to aminoglycosides, requiring much higher concentrations of aminoglycosides to kill them, and therefore can be selected during treatment.[82] Resistance developed by chromosomal means is minimal and develops slowly for most of the aminoglycosides, with the exception of streptomycin or dihydrostreptomycin; resistance to streptomycin can occur from a single-step mutation.[82]

Subinhibitory and inhibitory aminoglycoside concentrations produce resistance in bacterial cells surviving the initial ionic binding.[87] This adaptive resistance is caused by decreased aminoglycoside transport into the bacteria.[82] Exposure to one dose of an aminoglycoside is sufficient to produce resistant variants of an organism with altered metabolism and impaired aminoglycoside uptake. In vitro, animal and clinical studies show that the resistance occurs within 1 to 2 hours of the first dose. The duration of adaptive resistance relates directly to the elimination $T_{1/2}$ of the aminoglycoside. With normal aminoglycoside pharmacokinetics, the resistance may be maximal for up to 16 hours after a single dose of aminoglycoside, followed by partial return of bacterial susceptibility at 24 hours and complete recovery at around 40 hours.[88] If the aminoglycoside is dosed multiple times a day or the drug concentration remains constant, as with a continuous infusion, adaptive resistance persists and increases. Adaptive resistance is likely to persist in peripheral compartments, which are often the site of infection, because of the persistence of aminoglycosides at these sites. Dose administration at 24-hour intervals or longer may increase efficacy by allowing time for adaptive resistance to reverse.[87,89,90] Some clinicians have expressed reservations about once-daily dosing when intestinal damage allows continued exposure to bacteria that may replicate during the prolonged periods of subtherapeutic aminoglycoside concentrations, but this has not been documented clinically.

4.2.11.4

PHARMACOKINETICS

4.2.11.4.1

Absorption

Table 4.2-3 gives the pharmacokinetics of gentamicin and amikacin in horses. Amikacin and gentamicin are absorbed well and rapidly from intramuscular and subcutaneous routes of administration but are not absorbed orally.[83]

4.2.11.4.2 Distribution

The aminoglycosides are polar antibiotics; therefore distribution is limited to the extracellular fluid space. The Vd in most species ranges from 0.15 to 0.3 L/kg but is higher in neonates.[91,92] Following parenteral administration, effective concentrations are obtained in synovial, perilymph, pleural, peritoneal, and 199
pericardial fluid.[93] Therapeutic concentrations are not achieved in bile, CSF, respiratory secretions, or 200
prostatic and ocular fluids.[83,94] Gentamicin does not cross the placenta of late-term mares.[95] The predominant site of drug accumulation is the renal cortex in most species. The following general gentamicin concentrations are reached over time with repeated doses, from highest to lowest concentrations: renal cortex to renal medulla to liver/lung/spleen to skeletal muscle.[83] Gentamicin is distributed into jejunal and colonic tissue with a peak gentamicin concentration of 4.13 μg/ml in the large colon and 2.26 μg/ml in the jejunum.[96]

TABLE 4.2-3 Pharmacokinetics of Aminoglycosides in Horses

DRUG	VOLUME OF DISTRIBUTION (L/kg)	HALF-LIFE OR MRT* (HOUR)	CLEARANCE (ml/min/kg)	DOSE† (mg/kg)

* *MRT,* Mean residence time.

† *IV,* Intravenous; *IM,* intramuscular.

In endotoxemia, gentamicin concentrations increase in serum from a fever-induced decrease in the volume of the extracelluar fluid compartment.[97] The administration of therapeutic fluids, similar to those that are used to treat colic, does not change the pharmacokinetics of concurrently administered gentamicin significantly.[98] The pharmacokinetics of gentamicin are unchanged in horses undergoing colic surgery.[99]

Peritoneal lavage had no effect on pharmacokinetics of gentamicin in healthy horses after abdominal surgery, in which localized nonseptic peritonitis was induced.[100]

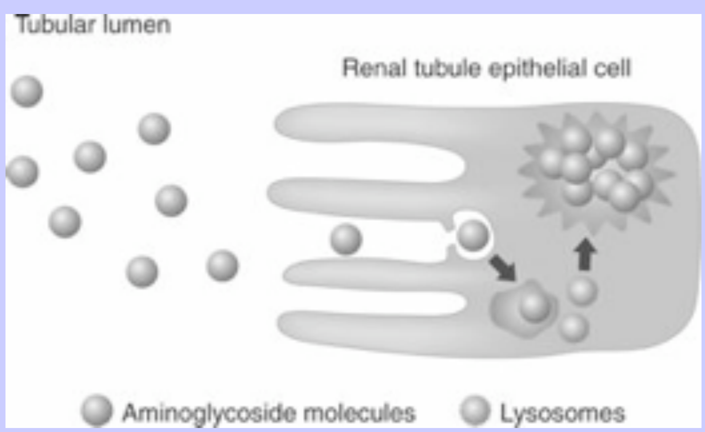
Endometrial tissue concentrations of gentamicin are higher than plasma concentrations after 7 days of intramuscular therapy with a dose of 5 mg/kg every 8 hours.[101] Intrauterine administration of 2 g of amikacin produces a peak of greater than 40 μg/g of endometrial tissue within 1 hour after infusion. Twenty-four hours after infusion, 2 to 4 μg of amikacin per gram of endometrial tissue is still present.[102] Intrauterine administration of 2.5 g of gentamicin once daily for 5 days resulted in endometrial tissue concentrations of 41.65 μg/g 24 hours after the last dose.[103]

Gentamicin diffuses into synovial fluid in normal horses and reaches a peak of 6.4 μg/ml at 2 hours with a single 4.4-mg/kg intravenous dose.[104] However, local inflammation may increase drug concentrations in the joint, and concentrations may increase with repeated doses. Intraarticular administration of 150 mg of gentamicin results in a peak synovial concentration of 1828 μg/ml 15 minutes after injection, and synovial concentrations remain greater than 10 μg/ml for at least 24 hours.[105] Regional perfusion techniques are excellent methods of local delivery of aminoglycosides and avoid the adverse effects of systemic therapy.[106–109] When intraosseous perfusion was compared with intravenous perfusion, each technique produced mean peak concentrations of amikacin ranging from 5 to 50 times that of recommended peak serum concentrations for therapeutic efficacy.[110] Gentamicin-impregnated polymethylmethacrylate beads also may be used to achieve high local concentrations of drug while avoiding systemic toxicity.[111–114]

4.2.11.4.3 Elimination

The aminoglycosides are eliminated almost exclusively by glomerular filtration.[83] The practical elimination 200
half-lives range from 1 to 3 hours in adult animals but increase in neonates or animals with renal 201
dysfunction. Renal accumulation results in extended withdrawal times for food animals.

Figure 4.2-4 Nephrotoxicity occurs from ionic binding of aminoglycoside molecules to polysaccharide cations on the proximal tubular epithelium, followed by pinocytosis and accumulation within lysosomes.



4.2.11.5 ADVERSE EFFECTS AND DRUG INTERACTIONS

4.2.11.5.1 Nephrotoxicity

The aminoglycosides enter the renal tubule after filtration through the glomerulus (Figure 4.2-4). From the luminal fluid the cationic aminoglycoside molecules bind to anionic phospholipids on the proximal tubular cells.[115] The aminoglycoside is taken into the cell via carrier-mediated pinocytosis and is translocated into cytoplasmic vacuoles, which fuse with lysosomes.[116] The drug is sequestered unchanged in the lysosomes. With additional pinocytosis, drug continues to accumulate within the lysosomes. The accumulated aminoglycoside interferes with normal lysosomal function, and eventually the overloaded lysosomes swell and rupture. Lysosomal rupture releases lysosomal enzymes, phospholipids, and the aminoglycoside into the cytosol of the proximal tubular cell, disrupting other organelles and causing cell death.[117]

The risk factors for aminoglycoside toxicity include prolonged therapy (greater than 7 to 10 days), acidosis and electrolyte disturbances (hypokalemia, hyponatremia), volume depletion (shock, endotoxemia), concurrent nephrotoxic drug therapy, preexisting renal disease, and elevated plasma trough concentrations.[83,118–122] Calcium supplementation can reduce the risk of nephrotoxicity.[123] Feeding the patient a high-protein, high-calcium diet such as alfalfa also can decrease the risk of nephrotoxicity, for protein and calcium cations compete with aminoglycoside cations for binding to renal tubular epithelial cells.[124] High dietary protein also increases glomerular filtration rate and renal blood flow, reducing aminoglycoside accumulation.[125]

Uptake and accumulation of aminoglycosides into renal tubular epithelium demonstrates saturable kinetics. Because nephrotoxicity is related to aminoglycoside accumulation in the renal proximal tubular cells, logically peak concentrations are not related to toxicity and longer dose intervals result in less total drug exposure to the renal brush border membrane. High-dose, once-daily dosing of aminoglycosides has now become common in human and veterinary medicine to take advantage of the concentration-dependent killing and long PAE of these drugs and avoid first exposure adaptive resistance and toxicity.[84,94,99,126]

4.2.11.5.2 Ototoxicity

Aminoglycoside ototoxicity occurs from the same mechanisms as nephrotoxicity.[127] Gentamicin damages the cochlear division of the eighth cranial nerve resulting in vertigo, whereas amikacin damages the auditory division of the eighth cranial nerve resulting in permanent deafness. This drug-specific toxicity may be caused by the distribution characteristics of each drug and concentration achieved in each sensory organ.[128]

4.2.11.5.3 Therapeutic Drug Monitoring

Individual horses can differ widely in the serum concentrations produced from the same aminoglycoside dosage regimen. When this unpredictability is combined with the often small difference between therapeutic and toxic serum concentrations, determining serum concentrations in a particular patient becomes valuable. The tendency is to underdose neonatal patients, especially those that are receiving aggressive fluid therapy.[129] To maximize efficacy and minimize toxicity, therapeutic drug monitoring of gentamicin or amikacin is

recommended. Peak concentrations are targeted to achieve an inhibitory quotient ratio of 10.[99] Because the trough concentration is associated with nephrotoxicity, trough concentrations are recommended to be less than 2 μg/ml for gentamicin and less than 5 μg/ml for amikacin before the next dose is administered.[83,88] To allow for the distribution phase, one should take the blood sample for the peak concentration at a half hour to 1 hour after intravenous administration and the trough sample before the next dose. One then can use the peak and trough concentrations to estimate the elimination $T_{1/2}$ for the individual patient. An increase in the elimination $T_{1/2}$ during therapy is a sensitive indicator of early tubular insult.[130] If one uses a once-daily regimen, a blood sample taken just before the next dose will be well below the recommended trough concentrations and may even be below the limit of detection of the assay. For these patients, an 8-hour postdose sample provides a more accurate estimate of the elimination $T_{1/2}$. 201

202

If therapeutic drug monitoring is unavailable, then once-daily high-dose therapy is recommended, and the practitioner can detect development of nephrotoxicity by an increase in urine γ-glutamyltransferase enzyme and an increase in the ratio of γ-glutamyltransferase to creatinine in the urine. The ratio may increase to 2 to 3 times baseline within 3 days of a nephrotoxic dose.[94,131] If these tests are not available, the development of proteinuria is the next best indicator of nephrotoxicity and is determined easily in a practice setting.[130] Elevations in serum urea nitrogen and creatinine confirm nephrotoxicity but are not seen for 7 days after significant renal damage has occurred.[92] Elimination half-lives of 24 to 45 hours have been reported in horses with renal toxicity, further prolonging the toxic exposure to the drug.[118] Although peritoneal dialysis is useful in lowering creatinine and serum urea nitrates, it may not be effective in significantly increasing the elimination of the accumulating aminoglycoside.[118] The ability of the horse to recover most likely depends on the type of medication exposure and the amount of healthy renal tissue remaining to compensate.

4.2.11.5.4 Neuromuscular Blockade

Neuromuscular blockade is a rare effect, related to blockade of acetylcholine at the nicotinic cholinergic receptor.[132] The effect occurs most often when anaesthetic agents are administered concurrently with aminoglycosides.[133] The clinician should treat affected patients promptly with parenterally administered calcium.[132]

4.2.11.5.5 Drug Interactions

Aminoglycosides are inactivated if combined in vitro with other drugs because of pH incompatibilities. The aminoglycosides are synergistic against streptococci, *Pseudomonas*, and other gram-negative bacteria if combined with β-lactam antibiotics because the antibiotic disrupts the bacterial cell wall.[82] Halothane anesthesia causes significant changes in the pharmacokinetics of gentamicin; total body clearance and Vd decrease, and the elimination $T_{1/2}$ increases.[134] A longer gentamicin dosing interval after anesthesia may help correct for the changes, but one seriously should consider choosing another antimicrobial. One should not use neuromuscular blocking agents or drugs with neuromuscular blocking activity concurrently with aminoglycosides because they can increase the risk of neuromuscular blockade, particularly during anesthesia.[82] One should avoid other nephrotoxic drugs when possible during aminoglycoside therapy. Concurrent administration of phenylbutazone with gentamicin decreases the elimination $T_{1/2}$ of gentamicin by 23% and decreases the Vd by 26% but does not affect the pharmacokinetics of phenylbutazone.[135]

Flunixin has no effect on the pharmacokinetics of gentamicin when administered concurrently to adult horses.[99]

4.2.11.6 FORMULATIONS

Gentamicin and amikacin are available as brand name and generic solutions for intrauterine infusion in mares. Although not labeled for other routes of administration, they commonly are administered to horses by intravenous, intramuscular, subcutaneous, intraarticular, and intraosseous routes. Gentamicin is also available in ophthalmic formulations for treating gram-negative keratitis.

4.2.11.7 CLINICAL USE

Gentamicin and amikacin are used commonly to treat serious gram-negative infections in horses. Amikacin is used in circumstances in which antimicrobial resistance to gentamicin has developed in gram-negative pathogens, but gentamicin usually retains greater activity against streptococci than amikacin. The aminoglycosides usually are administered concurrently with β-lactam antimicrobials for a possible synergistic effect. However, using aminoglycosides to treat infection in horses has been tempered by toxicity considerations. Use of the aminoglycosides also is limited by their poor penetration of cellular membranes and inactivation in the local environment at the therapeutic site.

4.2.12 Chloramphenicol and Florfenicol

Chloramphenicol was isolated in 1947 from a soil actinomycete from Venezuela. Florfenicol is a fluorinated derivative of chloramphenicol.

4.2.12.1 MECHANISM OF ACTION

Chloramphenicol and florfenicol are bacteriostatic antibiotics that inhibit protein synthesis by binding to ribosomal subunits of susceptible bacteria, leading to the inhibition of peptidyl transferase and thereby preventing the transfer of amino acids to growing peptide chains and subsequent protein formation.[136] These antibiotics have a wide spectrum of activity, including streptococci, staphylococci, anaerobes, *Haemophilus, Salmonella, Pasteurella, Mycoplasma*, and *Brucella* spp. Florfenicol has activity against chloramphenicol-resistant strains of *E. coli, Klebsiella, Proteus, Salmonella*, and *Staphylococcus aureus*. These antibiotics are also active against rickettsia, chlamydia, and *Hemobartonella*.[137]

4.2.12.2 MECHANISMS OF RESISTANCE

Bacterial resistance to chloramphenicol occurs from plasmid-mediated bacterial production of acetylase enzymes. Acetylation of hydroxyl groups prevents drug binding to the 50-S ribosomal subunit. Florfenicol has a fluorine atom instead of the hydroxyl group located at C-3 in the structure of chloramphenicol and 202
thiamphenicol. Initially, florfenicol was less susceptible to deactivation by bacteria with plasmid-transmissible 203
resistance to chloramphenicol.[138] Recently, new resistances to chloramphenicol and florfenicol have been identified in cattle pathogens.[139,140]

4.2.12.3 PHARMACOKINETICS

4.2.12.3.1 Absorption

Chloramphenicol and florfenicol are absorbed rapidly and extensively after oral administration. The oral bioavailability of chloramphenicol in foals is 83%[141] but is only 40% after a single administration in mares, and bioavailability declines to 20% after five doses.[142] The oral bioavailability of florfenicol in horses is 81%.[143] The commercially available formulation of florfenicol is a long-acting product for cattle and is characterized by delayed absorption and low plasma concentrations.[144]

4.2.12.3.2 Distribution

Because of high lipid solubility and low protein binding, chloramphenicol and florfenicol diffuse throughout the body. The highest drug levels occur in the liver and kidney, but therapeutic drug concentrations occur in most tissues and fluids, including ocular humor and synovial fluid.[137] Chloramphenicol may achieve concentrations up to 50% of plasma concentrations in the CSF when the meninges are normal and more if inflammation is present.[145] Florfenicol does not penetrate the blood-brain barrier as readily as chloramphenicol.[146] The Vd of chloramphenicol is 2.83 L/kg in horses[147] and 1.6 L/kg in neonatal foals.[141] The Vd of florfenicol is 0.72 L/kg in horses.[143] The degree of protein binding of chloramphenicol in horses is 30%,[148] and florfenicol has a low degree of protein binding in cattle.[149]

4.2.12.3.3 Elimination

In most species, these drugs are eliminated by renal excretion of parent drug and by hepatic glucuronide conjugation and elimination in feces. The elimination $T_{1/2}$ of chloramphenicol in foals older than 7 days and adult horses is less than 1 hour.[141,147,148,150,151] In 1-day-old foals the elimination $T_{1/2}$ is 5.3 hours, indicating the immaturity of the hepatic metabolism capacity of the foal.[150] Florfenicol has an elimination $T_{1/2}$ of 1.8 hours in horses after intravenous administration.[143] The long-acting formulation for cattle is eliminated slowly because of slow absorption from the intramuscular injection site (flip-flop kinetics).[144]

4.2.12.4 ADVERSE EFFECTS AND DRUG INTERACTIONS

Because these drugs are protein synthesis inhibitors, a dose-related anemia and pancytopenia are associated with chronic therapy (>14 days), causing a decrease in protein synthesis in the bone marrow. Florfenicol is more likely than chloramphenicol to cause reversible bone marrow suppression with chronic dosing.[146] In human beings an idiosyncratic aplastic anemia occurs with exposure to chloramphenicol.[152] The reaction is rare (1 in 30,000) and not dose-related. Toxic effects are related to the presence of the paranitro group on the chloramphenicol molecule. This reaction does not occur with florfenicol because it lacks the paranitro group. Chloramphenicol is a hepatic microsomal enzyme inhibitor that decreases the clearance of other drugs metabolized by the same cytochrome P-450 enzymes including phenytoin, phenobarbital, pentobarbital, phenylbutazone, xylazine, and cyclophosphamide.[137,153,154] Whether florfenicol affects the metabolism of other drugs is not known.

Although chloramphenicol is well tolerated by horses, florfenicol alters fecal consistency with single doses administered intravenously, orally, or intramuscularly.[143] In a chronic dosing study with the cattle intramuscular formulation, all horses remained clinically normal but had dramatic alterations in enteric flora. *Salmonella* spp., *E. coli*, and *Clostridium perfringens* in these horses rapidly developed resistance to florfenicol.[144]

Chloramphenicol may suppress antibody production if given before an antigenic stimulus and may affect vaccination response.[137] This effect has not been reported for florfenicol. One should not administer chloramphenicol or florfenicol concurrently with penicillins, macrolides, aminoglycosides, or fluoroquinolones. Chloramphenicol or florfenicol may antagonize the activity of penicillins or aminoglycosides, and they act on the same ribosomal site as the macrolides. Inhibition of protein synthesis by chloramphenicol or florfenicol interferes with the production of autolysins necessary for cell lysis after fluoroquinolones interfere with DNA supercoiling.

4.2.12.5 FORMULATIONS

Chloramphenicol sodium succinate is a water soluble formulation for intravenous use and is hydrolyzed to chloramphenicol in the liver. Chloramphenicol free base and chloramphenicol palmitate are available for oral administration. The chloramphenicol palmitate is hydrolyzed in the gastrointestinal tract to chloramphenicol. Ophthalmic formulations of chloramphenicol are also available. Florfenicol is only available as a cattle product in three carriers (2-pyrrolidone, propylene glycol, and polyethylene glycol) to give it a long-acting effect.

4.2.12.6 CLINICAL USE

Chloramphenicol is banned for use in any type of food animal because it causes idiosyncratic aplastic anemia in human beings. Chloramphenicol is used in small animals and horses for a variety of bacterial infections, especially where penetration into the CNS is desired, but one should take appropriate precautions in handling the product to prevent human exposure. One should not use florfenicol routinely in horses because of its 203
effects on gastrointestinal flora and the clinical limitations of the long-acting cattle formulation. 204

4.2.13 Potentiated Sulfonamides

The sulfonamides are a group of organic compounds with chemotherapeutic activity (hence, they are antimicrobials, not antibiotics). They have a common chemical nucleus that is related closely to *p*-aminobenzoic acid, an essential component in the folic acid pathway of nucleic acid synthesis. Sulfonamides are combined with diaminopyrimidines such as trimethoprim and pyrimethamine, which inhibit an essential step further along the folate pathway. The potentiated sulfonamides are remarkably synergistic and nontoxic and so are used commonly in equine medicine. Their use is complicated by differences in pharmacokinetics between trimethoprim/pyrimethamine and the various sulfonamides used in the combinations.

4.2.13.1 MECHANISM OF ACTION

The sulfonamides inhibit the bacterial enzyme dihydropteroate synthetase in the folic acid pathway, thereby blocking bacterial nucleic acid synthesis. Sulfonamides substitute for PABA, preventing its conversion to

dihydrofolic acid. Alone, this action is considered bacteriostatic. Because the activity is by competitive substitution, the sulfonamide tissue concentration must be kept high enough to prevent bacterial access to PABA. Therefore the sulfonamides are ineffective in pus and necrotic tissue, which provide additional sources of PABA to the bacteria. The sulfonamides are nontoxic to mammalian cells because they use dietary folate for synthesis of dihydrofolic acid and do not require PABA. The addition of trimethoprim or pyrimethamine to a sulfonamide creates a bactericidal combination. Trimethoprim inhibits bacterial folic acid synthesis at the next step in the folic acid sequence, inhibiting the conversion of dihydrofolic acid to tetrahydrofolic acid by inhibiting dihydrofolate reductase. This enzyme is present in bacterial and mammalian cells, but the bacterial enzyme is inhibited at much lower concentrations than necessary to inhibit the mammalian enzyme.[155] The minimum inhibitory concentrations against specific susceptible bacteria for each drug generally decrease when the antimicrobials are administered in the potentiated sulfonamide combination. The resistance developed to the potentiated sulfonamides is lower than that to each individual drug; this is an important benefit because resistance to sulfonamides is common and resistance develops rapidly to diaminopyrimidines when used alone.[156]

The potentiated sulfonamides have a broad spectrum of activity. Bacteria that are usually susceptible include *Streptococcus, Proteus, E. coli, Pasteurella, Haemophilus*, and *Salmonella* spp. Staphylococci, anaerobes, *Nocardia, Corynebacterium, Klebsiella*, and *Enterobacter* are susceptible but may become resistant. *Pseudomonas* spp., *Bacteriodes* spp., and enterococci are usually resistant.[40,157,158] Other significant organisms that are susceptible to potentiated sulfonamides include protozoa *(Toxoplasma gondii, Sarcocystis neurona)* and coccidia. Pyrimethamine is more effective against protozoa than trimethoprim.[156] The potentiated sulfonamides are formulated at a fixed ratio of 1:5 of trimethoprim to sulfonamide. The optimum concentration for bactericidal action is 1:20.[155] When and where this optimum concentration is achieved is difficult to predict in vivo, but a 1:20 ratio is used in susceptibility testing.[159]

4.2.13.2

MECHANISMS OF RESISTANCE

Bacterial resistance to the sulfonamides is common and may be from chromosomal mutations or may be mediated by plasmids. Chromosomal mutations can lead to bacterial hyperproduction of PABA, which overcomes the competitive substitution of the sulfonamides. Plasmid-encoded resistance results in a bypass of the drug-sensitive step by production of altered forms of the dihydropteroate synthetase enzyme with a lower affinity for sulfonamides. Resistance to trimethoprim usually occurs by plasmid-encoded production of trimethoprim-resistant dihydrofolate reductase. Other resistance mechanisms include excessive bacterial production of dihydrofolate reductase and reduction in ability of drug to penetrate the bacterial cell wall.[155] Cross-resistance between sulfonamides is considered complete and often occurs between pyrimidines. Resistance to the trimethoprim-sulfonamide combinations develops slowly but is now common among equine bacterial isolates.[160,161]

4.2.13.3

PHARMACOKINETICS

Pharmacokinetics of the potentiated sulfonamides are complicated by the distinct differences between disposition of trimethoprim/pyrimethamine and the various sulfonamides. When sulfonamides and diaminopyrimidines are administered concurrently to horses, the pharmacokinetics of each drug appear to be unaffected by the presence of the other. Table 4.2-4 gives the pharmacokinetics of specific potentiated sulfonamide combinations in horses. Although the potentiated sulfonamides frequently are used interchangeably, pharmacokinetics studies show that they are not bioequivalent in horses.

4.2.13.3.1

Absorption

In general, potentiated sulfonamides are absorbed readily from the gastrointestinal tract of horses but may be affected by feeding.[162–164] For trimethoprim and sulfachlorpyridazine, peak plasma concentrations and bioavailabilities are reduced significantly when the drug is mixed with concentrate compared with nasogastric administration.[165] Both drugs also demonstrate a biphasic absorption pattern, which appears to be caused by a portion of the trimethoprim and sulfachlorpyridazine dose binding to feed, with a second absorption phase occurring in the large intestine.[166] Bioavailability after intrauterine administration is 23% to 43% for trimethoprim and 29% to 34% for sulfadoxine. After intrauterine administration, trimethoprim and sulfadiazine are detected in the milk.[167] The oral bioavailability of pyrimethamine is 56% in horses.[168]

204

205

TABLE 4.2-4 Pharmacokinetics of Trimethoprim, Pyrimethamine, and Sulfonamides in Horses

DRUG	VOLUME OF DISTRIBUTION (L/kg)	HALF-LIFE OR MRT[*] (HOUR)	PROTEIN BINDING (%)	CLEARANCE (ml/min/kg)	DOSE[†] (mg/kg)
Trimethoprim	—	2.4	—	—	PO: 5
Sulfadiazine[163]		7.4			PO: 25
Trimethoprim	2.0	2.8	35	8.8	IV: 2.5
Sulfadiazine[185]	0.5	4.6	20	1.5	IV: 12.5
Trimethoprim	1.5	3	50	—	IV: 8
Sulfadoxine[173]	0.39	14	14–72		IV: 40
Trimethoprim	2.8	3.4	—	11	IV: 7.5
Sulfamethoxazole[192]	0.5	4.8	—	1.4	IV: 36.5
Trimethoprim	1.6	1.9	—	13	IV: 2.5
Sulfamethoxazole[170]	0.33	3.5	—	1.3	IV: 12.5
Trimethoprim	1.5	2.6	—	7.7	IV: 5
Sulfachlorpyridazine[165]	0.26	3.8	—	2.6	IV: 25
Pyrimethamine[168]	1.5	12	—	1.6	IV, PO: 1
Sulfadiazine[174]	0.4	3.8	43	2.3	IV: 20

Sulfamethazine[162]	0.63	11.4	—	0.8	IV: 160
Sulfamethazine[174]	0.33	5.4	69	0.9	IV: 20

* *MRT,* Mean residence time.

† *PO,* Oral; *IV,* intravenous.

4.2.13.3.2 Distribution

The sulfonamides are weak acids and are hydrophilic; therefore they distribute well in extracellular and interstitial fluids and typically have values for Vd of 0.3 to 0.7 L/kg. Initial concentrations of sulfonamides in tissues are generally lower than those in plasma. The diaminopyrimidines are lipophilic weak bases and penetrate tissues better than sulfonamides, resulting in values for Vd of 1.5 to 2.7 L/kg and higher tissue concentrations than plasma concentrations.[155] Distribution of potentiated sulfonamides has been investigated broadly in the horse. Sulfadiazine and trimethoprim[169] and sulfamethoxazole and trimethoprim[170,171] are well distributed into peritoneal fluid, CSF, synovial fluid, and urine. Inflammation in the meninges or synovium does not affect distribution into the respective fluids significantly. After repeated doses, sulfamethoxazole, unlike trimethoprim, accumulates in the CSF.[170] CSF concentrations of pyrimethamine reach 25% to 50% of serum concentrations but do not appear to accumulate in horses with daily dosing.[172]

Sulfonamides can be highly bound to plasma proteins, but the extent of binding depends on the species, drug, and concentration. In the horse, degree of protein binding varies from 33% for sulfaphenazole to 93% for sulfamethoxine.[155] Approximately 50% of trimethoprim is protein bound, and binding is independent of plasma concentration.[173] Although only free drug is available for antimicrobial action, protein-bound drug serves as a reservoir and extends the duration of action of these drugs.

4.2.13.3.3 Metabolism

The liver metabolizes diaminopyrimidines and sulfonamides, usually by acetylation, aromatic hydroxylation, and glucuronidation.[155] The acetylated, hydroxylated, and conjugated forms of the sulfonamides are significantly less microbiologically active than their parent compounds. The precise metabolic pathways for trimethoprim or pyrimethamine have not been elucidated.[171] Metabolites may compete with the parent drug for involvement in folic acid synthesis. They have little detrimental effect on bacteria, so their presence can decrease the activity of the remaining parent drug.[174]

4.2.13.3.4 Elimination

Sulfonamides are excreted primarily in urine, but excretion in feces, bile, milk, sweat, and tears also occurs. Renal excretion of unchanged drug and metabolites occurs by glomerular filtration and active tubular secretion.[155] Reabsorption occurs in the distal tubule by passive diffusion. Because most sulfonamides are weak acids, alkaline urine increases their ionization and elimination. Renal excretion of trimethoprim 205
occurs by glomerular filtration, active tubular secretion, and reabsorption. In horses a large percentage of 206
trimethoprim appears to be metabolized before elimination in urine (46%) and feces (52%).[173] Urine pH, plasma concentration, and extent of diuresis affect the clearance of the diaminopyrimidines. In contrast to the sulfonamides, alkaline urine increases the reabsorption of the basic trimethoprim.[175]

4.2.13.4

ADVERSE EFFECTS AND DRUG INTERACTIONS

The potentiated sulfonamides are noted for their widely varying adverse effects. Crystalluria, hematuria, and renal tubular obstruction can result from poorly soluble sulfonamides, especially in dehydrated patients with acidic urine.[155] However, the lower doses of sulfonamide used in the potentiated sulfonamide combinations makes crystallization less likely to occur than with sulfonamides administered alone. Local infusion of potentiated sulfonamides into the uterus of mares causes irritation of the endometrium and a decreased pregnancy rate.[167] Intramuscular administration causes tissue irritation from the organic solvents, high concentration, and high pH of the formulations and should be avoided. Intravenous administration must be slowly and carefully done. Rapid administration is associated with thrombophlebitis and anaphylaxis.[155,176] The concurrent use of potentiated sulfonamides with detomidine is contraindicated, because the potentiated sulfonamide appears to sensitize the myocardium and results in cardiac dysrhythmias and hypotension that may be fatal.[177,178] The procaine in procaine penicillin G is a PABA analog and may reduce efficacy if used concurrently with potentiated sulfonamides.[41]

4.2.13.4.1

Folate Antagonism Effects

The nonregenerative anemias seen in response to long-term administration of potentiated sulfonamides are believed to be related to folate reduction with long-term, high-dose administration, such as for treatment of equine protozoal encephalomyelitis. Concurrent therapy with trimethoprim and pyrimethamine does not increase the efficacy against protozoa and is suspected to increase the incidence of side effects because of folate reduction. Supplementation with oral folic acid often is recommended for horses for long-term potentiated sulfonamide therapy.[179] The oral administration of folic acid to pregnant mares being treated for equine protozoal encephalomyelitis may not protect the fetus from the effects of folate deficiency. Mares have delivered foals with congenital defects after oral administration of potentiated sulfonamides. These mares also had been given oral folic acid and vitamin E during the period of antibiotic treatment. Each of three mares on this dosage regimen produced a foal with renal hypoplasia or nephrosis and bone marrow aplasia or hypoplasia. In mares and foals, serum folate concentrations were below the laboratory reference range, and in two foals, folate was less than 30% of the minimum reference range.[180] One should consider the risk of congenital defects when treating pregnant mares with pyrimethamine and sulfonamide. Treatment with trimethoprim-sulfamethoxazole and pyrimethamine does not affect semen quality, testicular volume, sperm production efficiency, erection, or libido of healthy stallions. However, treatment may induce changes in copulatory form and agility and alter the pattern and strength of ejaculation.[181] Stallions that develop neurologic signs during treatment should be used with caution for breeding. Trimethoprim-sulfamethoxazole has been associated with immune-mediated hemolytic anemia in a horse.[182]

4.2.13.4.2

Effects on Gastrointestinal Flora

The effects of potentiated sulfonamides on normal gastrointestinal flora are controversial. In some studies, potentiated sulfonamides alone[183] or with concurrent penicillin therapy[16] are associated with diarrhea in horses. Other studies show little effect on fecal flora.[184,185] The likelihood of any antimicrobial therapy causing diarrhea in a horse depends on several factors, including the antibacterial spectrum of the drug and the drug concentrations achieved in the gastrointestinal tract. The presence or absence of potential pathogens in the composition of the microflora of the horse and the presence of antimicrobial-resistant

pathogens in the hospital or clinic environment are also important factors in the incidence of gastrointestinal disturbances.

4.2.13.5
FORMULATIONS

Trimethoprim-sulfadiazine is available as a 48% injectable solution for intravenous administration in horses and is also available in oral paste and powder formulations for horses. Human generic tablets of trimethoprim-sulfamethoxazole commonly are administered to horses. Pyrimethamine-sulfadiazine formulations are routinely available through compounding pharmacies.

4.2.13.6
CLINICAL USE

Applying pharmacokinetic principles to determine drug dosage regimens for the potentiated sulfonamides is difficult. Different pathogens have varying MIC values, and the optimal ratio of trimethoprim or pyrimethamine to sulfonamide also varies between bacteria and protozoa. The most important component of the formulation for efficacy appears to be the diaminopyrimidine, and the choice of sulfonamide may not be nearly as important. Therefore considerable controversy exists regarding the dosage regimen of these combinations. The veterinary products are labeled for once-daily administration, but studies indicate that twice-daily dosing is better for attaining therapeutic plasma concentrations.[185,186] 206

207

4.2.14
Tetracyclines

Tetracycline was discovered after a team of workers examined 100,000 soil samples from around the world. Tetracycline derivatives include *oxytetracycline, chlortetracycline, doxycyline*, and *minocycline*. Oxytetracycline and doxycycline are used in horses.

4.2.14.1
MECHANISM OF ACTION

The tetracyclines bind to the 30-S ribosomal subunit and interfere with bacterial protein synthesis. They are bacteriostatic at usual therapeutic concentrations, but bactericidal at high concentrations. Drug entry into the bacteria is by an energy-dependent mechanism. Mammalian cells do not possess the tetracycline transport mechanism. Tetracyclines are most active at an acidic pH. The tetracyclines are broad spectrum in activity; they are effective against gram-positive and gram-negative bacteria, as well as *Chlamydia, Mycoplasma, Rickettsia*, and some protozoa *(Haemobartonella, Anaplasma)*.[187] Their activity against staphylococci is limited, and they are not active against group D streptococci (enterococci). *Pseudomonas, Escherichia coli, Klebsiella*, and *Proteus* are usually resistant.[188,189] Most anaerobes are susceptible to doxycycline.[187] In vitro concentrations of oxytetracycline greather than 0.01 μg/ml effectively suppress growth of *Ehrlichia risticii*.[190]

4.2.14.2
MECHANISMS OF RESISTANCE

Widespread acquired resistance in many pathogens limits the clinical usefulness of the tetracyclines. Resistance occurs from plasmid-mediated failure in the active transport of the drug into the bacterial cell and increased efflux from the cell. Another major mechanism of resistance involves cytoplasmic production of a protein that protects the ribosome from tetracycline action.[187]

4.2.14.3 PHARMACOKINETICS

4.2.14.3.1 Absorption

Oral absorption of oxytetracycline is erratic and is not recommended in horses because of adverse effects on gastrointestinal flora.[184] At a dose of 10 mg/kg, doxycycline produced serum, synovial fluid, peritoneal fluid, and endometrial tissue concentrations greater than 0.25 μg/ml, suggesting effective therapy for gram-positive infections.[191] A precise bioavailability cannot be determined, because intravenous administration of doxycycline causes cardiac toxicity.[192] The long-acting formulation of oxytetracycline in polyethylene glycol has a bioavailability of 83% after intramuscular injection in horses.[193]

4.2.14.3.2 Distribution

The tetracyclines are well distributed to most tissues, except the CNS. Therapeutic levels may be achieved, however, when the meninges are inflamed. Tetracyclines readily diffuse into milk.[187] Oxytetracycline reaches 50% of plasma concentrations in synovial fluid and peritoneal fluid. Oxytetracycline concentrations in urine are high, with peak concentrations greater than 1500 μg/ml.[194] The Vd of oxytetracycline in neonatal foals is 2 L/kg[195] and in adult horses is 0.34 to 0.95 L/kg.[193,196] The apparent Vd of doxycycline in horses is 25 L/kg, indicating a high lipid solubility and tissue penetration.[191] Synovial and peritoneal fluids achieve the same doxycycline concentrations as plasma, and endometrial tissue concentrations are more than twice plasma concentrations. Doxycycline is not detectable in CSF after oral administration.[191] Oxytetracycline is 50% protein bound in horses.[197] Although not reported for horses, doxycycline is highly protein bound (90%) in other species.[187]

4.2.14.3.3 Elimination

The tetracyclines are not known to be biotransformed to any significant extent before elimination. Oxytetracycline is eliminated unchanged in urine primarily by glomerular filtration. Unmetabolized drug also is eliminated with bile into the gastrointestinal tract and may undergo enterohepatic recirculation, prolonging its effects.[187] Doxycycline is excreted primarily into the feces via nonbiliary routes in an inactive form. Therefore doxycycline does not accumulate in patients with renal insufficiency.[198] The clearance of oxytetracycline is 3.3 ml/min/kg in foals[195] and 2.2 ml/min/kg in adult horses.[193] When administered intravenously, the elimination $T_{1/2}$ of oxytetracycline is 7 hours in foals[195] and 6 hours in horses.[193] Because of flip-flop kinetics, the elimination $T_{1/2}$ is 22 hours after intramuscular administration of oxytetracycline in polyethylene glycol.[193]

4.2.14.4 ADVERSE EFFECTS AND DRUG INTERACTIONS

4.2.14.4.1 Gastrointestinal Effects and Interactions

Calcium-containing products (milk, antacids) or other divalent cations chelate with tetracyclines and interfere with gastrointestinal absorption.[187] Doxycycline is less likely than the older tetracyclines to form chelation complexes with divalent and trivalent metals, so less interference occurs with oral absorption by calcium or other substances.[198]

The clinical use of oxytetracycline in horses is controversial because of reports of adverse gastrointestinal effects. However, adverse effects also were associated with excessive dosage,[199] concomitant use of other antimicrobials, and stressors such as surgery and transport.[200–203] Anecdotally, oxytetracycline therapy has been used successfully in equine practice, and the recognition of the equine ehrlichial diseases has increased oxytetracycline use in horses.[204,205] In a chronic dosing study using a long-acting formulation of 207
oxytetracycline, no deleterious effects on fecal flora were detected and treated horses remained clinically 208
normal.[206] Doxycycline is less likely to cause adverse gastrointestinal effects because it is bound in an inactive form in the intestines.[187]

4.2.14.4.2 Renal Effects

Renal tubular necrosis from oxytetracycline is associated with high doses, outdated parenteral products, endotoxemia, dehydration and hypovolemia, and concurrent pigment nephropathy.[187,207] In normal foals, high-dose intravenous oxytetracycline administration for the correction of flexural deformities does not cause renal toxicity.[208] Oliguric renal failure developed in a foal given 70 mg/kg of oxytetracycline intravenously for a flexural deformity with concurrent neonatal isoerythrolysis.[207]

4.2.14.4.3 Cardiovascular Effects

Rapid intravenous administration of oxytetracycline results in hypotension and collapse, which is attributed to intravascular chelation of calcium and/or decreased blood pressure from the drug vehicle (propylene glycol). Pretreatment with calcium borogluconate intravenous prevents collapse.[209,210] Rapid intravenous administration of doxycycline to horses causes tachycardia, systemic arterial hypertension, collapse, and death.[192,211] One suggestion is that this reaction is caused by chelation of intracellular calcium, resulting in neuromuscular blockade of the myocardium.

4.2.14.4.4 Musculoskeletal Effects

Intramuscular injection of long-acting oxytetracycline formulations cause localized pain and swelling at the injection site.[187,206] Oxytetracycline causes flexor tendon relaxation; this effect has been used to treat foals with flexural deformities.[212,213] The mechanism of oxytetracycline-induced relaxation is unknown but may be related to calcium-chelation or neuromuscular blockade.

4.2.14.5 FORMULATIONS

Injectable oxytetracycline products are formulated as short- or long-acting products. The short-acting solutions are in propylene glycol and have concentrations of 50 or 100 mg/ml. The long-acting solutions are in 2-pyrrolidone or polyethylene glycol and have a concentration of 200 mg/ml. The polyethylene glycol formulation is less irritating than the 2-pyrrolidone formulation. The long-acting formulations may be administered by slow intravenous injection but the long-acting effect is lost.[193]

4.2.14.6 CLINICAL USE

Oxytetracycline is the drug of choice for Potomac horse fever *(Ehrlichia risticii)* and equine ehrlichiosis *(E. equi)*.[204,205,214,215] Oxytetracycline also is used to treat contracted flexor tendons in foals and calves.[212,213] Its use for other microbial infections in horses is controversial because of concerns of adverse gastrointestinal effects and widespread antimicrobial resistance. Doxycycline also is indicated for rickettsial diseases in horses and may be a suitable oral alternative to oxytetracycline.

4.2.15 Macrolides and Azalides

The macrolide antibiotics include *erythromycin, clarithromycin, tylosin, tilmicosin*, and *tiamulin*. Azalides, such as *azithromycin*, have a similar mechanism of action but have a methylated nitrogen in the macrocyclic ring. Because of adverse gastrointestinal effects, one should avoid using these drugs for horses, except for erythromycin and azithromycin in foals.

4.2.15.1 MECHANISM OF ACTION

The macrolides and azalides bind to the 50-S ribosomal subunit in a manner similar to chloramphenicol and florfenicol and interfere with protein synthesis. They usually are considered bacteriostatic but may be bactericidal at high concentrations. Macrolides are not effective against gram-negative bacteria, except some strains of *Pasteurella* and *Haemophilus* in cattle.[216] Azithromycin is more active than the macrolides against gram-negative bacteria and anaerobes.[217] Susceptible bacteria include staphylococci, streptococci, *Campylobacter jejunii, Clostridium, Rhodococcus equi, Mycoplasma* spp., and *Chlamydia* spp.[40,189,218] Optimum antimicrobial activity of these weak bases is at alkaline pH; therefore they have reduced activity in acidic environments (pus, abscesses) but may be clinically effective in high concentrations because of ion trapping. Erythromycin also has nonantimicrobial effects on host cell metabolism, inflammatory mediators, and gastrointestinal motility.[219,220]

4.2.15.2 MECHANISMS OF RESISTANCE

The routine use of the macrolides is limited because bacterial resistance develops quickly from repeated exposure.[221] Mechanisms of resistance include decreased drug entry into bacteria, inability to bind to the bacterial 50-S ribosomal subunit, and plasmid-mediated production of esterases.[24,221] Recently, 13% of *R. equi* isolates were found to be resistant to erythromycin.[222] Extensive cross-resistance occurs between the macrolides.[216]

4.2.15.3 PHARMACOKINETICS

4.2.15.3.1 Absorption

Erythromycin is available for oral administration as enteric coated erythromycin base, erythromycin esters (ethylsuccinate or estolate) or erythromycin salts (phosphate or stearate). Because of expense, many practitioners administer the drug as crushed enteric coated tablets of erythromycin base. However, 208
erythromycin base is degraded in the stomach because of the gastric acid. The esterified formulations are 209
absorbed intact and must be hydrolyzed to the active erythromycin A. The erythromycin salts are absorbed unchanged.[223] The oral bioavailability of erythromycin base is 17% in fasted foals, with most of the drug being degraded and absorbed as the microbiologically inactive anhydroerythromycin A.[224] Microencapsulation of the base improves the oral bioavailability of erythromycin base to 26% in fasted foals but remains only 7.7% in fed foals.[225] The oral bioavailability of erythromycin estolate in fasted foals is 36% but only 16% for erythromycin phosphate. The estolate formulation appears to have the best pharmacokinetic profile in foals.[226] Because of injection site irritation, intramuscular administration of erythromycin is not recommended in horses. The oral bioavailability of azithromycin in foals is approximately 50%.[227]

4.2.15.3.2 Distribution

The macrolides are well distributed into most tissues. Erythromycin and azithromycin concentrate in leukocytes, making them effective against intracellular pathogens such as *R. equi*.[228,229] Because macrolides are weak bases, they are ion trapped in milk, CSF, and gastric fluids. The Vd for erythromycin is 2.7 L/kg in foals.[224] Azithromycin is known for its high degree of lipid solubility, and the Vd of azithromycin in foals is 18.6 L/kg. Peritoneal and synovial fluid concentrations of azithromycin parallel serum concentrations. Bronchoalveolar cell and pulmonary epithelial lining fluid concentrations are fifteen- to 170-fold and one- to sixteenfold higher than concurrent serum concentrations, respectively.[227]

4.2.15.3.3 Elimination

Erythromycin is metabolized extensively, with much of the parent drug and active metabolite excreted into the bile, resulting in an elimination half-life of 1 to 2 hours.[224–226,230] Erythromycin inhibits the metabolism of a number of other drugs by interfering with cytochrome P-450 enzymes.[216] The degradation product anhydroerythromycin A also is a potent inhibitor of cytochrome P-450–mediated metabolism.[219] Erythromycin undergoes enterohepatic cycling.[216] Azithromycin is not highly metabolized and is primarily eliminated in bile.[216] The elimination $T_{1/2}$ is 20.3 hours in foals.[227]

4.2.15.4 ADVERSE EFFECTS AND DRUG INTERACTIONS

The use of erythromycin in horses is associated with a number of adverse effects. After erythromycin came into clinical use in the 1950s, the gastrointestinal side effects that frequently accompany therapy became apparent. Macrolide antibiotics, including erythromycin and clarithromycin, are motilin receptor agonists.

They also appear to stimulate motility via cholinergic and noncholinergic neuronal pathways. At microbially ineffective doses, they stimulate migrating motility complexes and antegrade peristalsis in the gastrointestinal tract.[220,231,232] When used at antimicrobial doses, erythromycin is associated with potentially fatal colitis from *Clostridium* spp.[233–235]

Erythromycin also is associated with acute respiratory distress syndrome, hyperthermia, gastroenteritis, and hepatotoxicity in foals.[219,236,237] The mechanism of hyperthermia in foals treated with erythromycin has not been elucidated but likely results from derangement of the hypothalamic temperature set-point.[236] One should take extreme care when administering erythromycin to foals with respiratory disease during periods of hot weather. Foals should not be left outside on hot, sunny days while receiving erythromycin therapy. Erythromycin also interferes with host cell metabolism and decreases inflammatory responses in airways, but the clinical significance of this has not been determined.[219]

Erythromycin is administered commonly with rifampin to take advantage of antimicrobial synergism and reduce the chance of resistance development.[14] Erythromycin may interact with other drugs metabolized by the same cytochrome P-450 enzyme system. Concurrent administration of erythromycin with theophylline results in doubling of plasma theophylline concentrations and can result in seizures in foals.[216]

Azithromycin is associated with fewer adverse effects than erythromycin in human beings.[217] No adverse reactions were detected during or after repeated intragastric administration of azithromycin in foals.[227]

4.2.15.5 FORMULATIONS

The base of erythromycin is unstable in gastric acid; therefore the base is formulated as enteric coated erythromycin tablets. Erythromycin stearate and erythromycin phosphate are insoluble salt formulations that disassociate in the intestine, allowing absorption of the free erythromycin base. Erythromycin ethylsuccinate and erythromycin estolate are ester formulations that are absorbed intact from the intestine; then plasma esterases release active drug. Erythromycin is available in an intramuscular formulation approved for cattle. Because of its highly irritating nature, intramuscular use is not recommended in horses and intravenous injection can be fatal. A human-labeled formulation of erythromycin lactobionate is available for intravenous use.

4.2.15.6 CLINICAL USE

Because of its association with potentially fatal adverse effects, erythromycin usually is limited to treatment of
R. equi infections in foals.[14,218,238–240] Erythromycin also has been shown to be an effective therapy of 209
Potomac horse fever[190,241] and equine proliferative enteropathy caused by *Lawsonia intracellulare*.[242] Its 210
motilin-like activity is exploited to treat adynamic ileus in horses.[220] Azithromycin recently has become an attractive alternative to erythromycin for treating *R. equi* infections in foals because of its pharmacokinetic profile, which allows once a day or every other day dosing, and an apparent reduced incidence of adverse effects.

4.2.16 Fluoroquinolones

The quinolones are a group of synthetic antimicrobials. The first was *nalidixic acid*, which was introduced in 1964. Nalidixic acid had good activity against gram-negative bacteria but had a low Vd and numerous adverse effects and was limited to treatment of urinary tract infections. Further chemical manipulation resulted in development of the fluorinated quinolones, which had extended antimicrobial activity with improved safety. Included in this group are *ciprofloxacin, enrofloxacin, danofloxacin, difloxacin, sarafloxacin, norfloxacin, orbifloxacin, marbofloxacin*, and *ofloxacin*. No fluoroquinolones are approved for use in horses, but because of their pharmacokinetics and antimicrobial activity, they are used commonly for serious gram-negative infections.[243]

4.2.16.1 MECHANISM OF ACTION

The fluoroquinolones have a unique mechanism of action for bacterial killing. The fluoroquinolones inhibit bacterial topoisomerase DNA gyrase (also known as topisomerase II). Bacteria have a single chromosome consisting of double-stranded DNA. Within the bacterial cell the chromosome is folded around an RNA core, and each fold is supercoiled. DNA gyrase, which has been found in every organism examined, is responsible for supercoiling the strand of bacterial DNA. The DNA gyrase structure has four subunits: two A monomers and two B monomers. The enzyme forms a heart-shaped molecule, with the A monomers forming atria and the B monomers forming ventricles. The bacterial DNA binds to the gyrase in the cleft between the A and B subunits. The DNA gyrase nicks double-stranded DNA, introduces negative supercoils, and seals the nicked DNA. The fluoroquinolones bind to the DNA-DNA gyrase complex and inhibit the DNA resealing, resulting in abnormal spatial DNA configuration, which leads to DNA degradation by exonucleases.[244]

Fluoroquinolone activity is concentration dependent. All of the fluoroquinolones are bactericidal; however, these drugs have an optimal concentration that is most bactericidal. Higher or lower drug concentrations result in reduced bactericidal activity. The DNA-DNA gyrase complex is thought to have two binding sites for fluoroquinolones. At low drug concentrations only one binding site is occupied, resulting in single-stranded nicks in the DNA. Reduced killing at high concentrations is thought to be caused by dose-dependent inhibition of RNA or protein synthesis. RNA and protein synthesis are required for production of bacterial autolysins, which are responsible for the fluoroquinolone-induced cell lysis.[244,245]

The fluoroquinolones are broad spectrum in activity against most gram-negative bacteria, some gram-positive bacteria, and *Mycoplasma, Chlamydia*, and *Rickettsia* spp. They are particularly effective against the enteric gram-negative pathogens, including some strains resistant to aminoglycosides and cephalosporins. Reported MICs are low, and MBCs are 1 to 2 times the MIC for most pathogens. They are usually active against staphylococci but have variable activity against streptococci and enterococci.[245] Most diagnostic laboratories use ciprofloxacin or enrofloxacin to determine pathogen susceptibility; however, MIC values vary among the fluoroquinolones. Ciprofloxacin has the greatest activity against *Pseudomonas* spp. Orbifloxacin has lower MIC values than enrofloxacin for the gram-negative bacteria *Actinobacillus equuli*, *Escherichia coli*, *Pasteurella* spp., and *Salmonella* spp. Enrofloxacin has lower MIC values for the gram-positive bacteria and *Pseudomonas* spp.[243]

Most fluoroquinolones are not active against anaerobic bacteria.[245] This susceptibility pattern may be a therapeutic advantage in treating enteric infections in horses, because gastrointestinal anaerobes rarely cause disease and usually are protective by competitively inhibiting colonization by pathogenic aerobic organisms.

The fluoroquinolones are concentrated within phagocytic cells. Uptake occurs by simple diffusion, and intracellular concentrations may be several times greater than plasma concentrations. Intracellular drug is microbiologically active against intracellular pathogens such as *Brucella* spp., *Mycoplasma* spp., and *Mycobacterium* spp.[245] Exposure of gram-negative bacteria to fluoroquinolones at concentrations several times the MIC for 1 to 2 hours results in a PAE with a recovery period of 1 to 6 hours. This effect suggests that fluoroquinolone dosage regimens can tolerate plasma concentrations below the MIC of the pathogen for extended periods of time without a reduction in efficacy.[244]

4.2.16.2 MECHANISMS OF RESISTANCE

Microbial resistance to the fluoroquinolones is caused by chromosomal mutations that alter bacterial DNA gyrase, decrease cell wall permeability, or increase fluoroquinolone efflux from the cell. Plasmid-mediated resistance has not been documented for the fluoroquinolones. The most common mechanism of resistance is from alteration of the bacterial DNA gyrase, resulting in decreased fluoroquinolone binding to the DNA-DNA gyrase complex. This occurs from point mutations in the genes coding for the enzyme structure, resulting in 210
physical obstruction for the fluoroquinolones as they bind to the DNA-DNA gyrase complex.[246] Gyrase 211
mutations confer high-level cross-resistance to all fluoroquinolones but are not associated with resistance to other unrelated antimicrobials.[247]

The fluoroquinolones must penetrate bacteria to reach the target DNA gyrase. The second mechanism of fluoroquinolone resistance is from decreased cell wall permeability.[245,246] The fluoroquinolones diffuse through porin channels in the outer membrane of gram-negative bacteria. The identified mutations result in a decrease in porin channel proteins, resulting in decreased uptake of the fluoroquinolones into the cell. *Pseudomonas* spp. resistance is associated with alterations in a wide range of outer membrane proteins. From these mutations the increase in the MICs of the fluoroquinolones is low (two- to thirty-twofold). However, cross-resistance with unrelated antibiotics occurs, most frequently with trimethoprim, tetracycline, chloramphenicol, and cefoxitin.[246]

The third mechanism for fluoroquinolone resistance is from increased fluoroquinolone efflux.[246] Efflux is the energy-dependent process of the inner bacterial membrane that exports drug into the periplasm or outside of the cell. This type of resistance occurs in staphylococci and streptococci and is associated with the presence of a resistance gene, *nor*A.[247] The degree of resistance conferred by increased fluoroquinolone efflux is less than the resistance caused by the DNA gyrase mutations, but the increase in MICs is sufficient for resistant mutants to arise during fluoroquinolone therapy.[246]

Because the fluoroquinolones have been used intensively in human medicine in the last 2 decades, high-level resistance has emerged in some pathogens. Because resistance is chromosomally mediated, chronic fluoroquinolone use encourages the development of resistance. In high-level resistant bacterial strains, one resistance mechanism alone is usually not responsible, rather two or three mechanisms of resistance operate together. In resistant *Staphylococcus aureus*, increased efflux often is coupled with a gyrase mutation.[247] In resistant *E. coli*, gyrase mutations usually are associated with changes in the outer membrane proteins.[248]

4.2.16.3 PHARMACOKINETICS

4.2.16.3.1 Absorption

The fluoroquinolones are absorbed well and rapidly from the gastrointestinal tract of monogastrics and preruminant calves. Enrofloxacin is more lipid soluble than ciprofloxacin and has a higher oral bioavailability than ciprofloxacin in horses and small animals. The oral bioavailability of ciprofloxacin is only 6.8% in adult ponies. The oral bioavailability of enrofloxacin is approximately 60% in adult horses and 42% in foals.[249,250] Antacids containing divalent cations (calcium, magnesium) chelate fluoroquinolones and reduce oral bioavailability.[245] Bioavailability from parenteral injection is nearly 100% for all fluoroquinolones, but intramuscular injections of enrofloxacin irritate tissues.[251]

4.2.16.3.2 Distribution

The fluoroquinolones are lipid soluble and well distributed to most tissues. The Vd of enrofloxacin is 2.3 L/kg in mares and 2.5 L/kg in foals.[249,251] The Vd of orbifloxacin in mares is 4 L/kg.[243] Tissue concentrations typically exceed plasma concentrations during therapy. High concentrations occur in the kidney, urine, liver, and bile. Therapeutic concentrations for gram-negative bacteria may be achieved in the CSF and ocular fluids.[243,252–254]

4.2.16.3.3 Elimination

The fluoroquinolones are excreted predominantly as unchanged drug in the urine by glomerular filtration and active tubular secretion.[244] Ciprofloxacin undergoes some sulfoxidation, and its metabolites also have antimicrobial activity. Enrofloxacin is metabolized (deethylated) to ciprofloxacin in horses, with serum ciprofloxacin concentrations reaching 20% to 35% of enrofloxacin concentrations.[251] The elimination $T_{1/2}$ of ciprofloxacin in ponies is 2.5 hours and in horses is 5 hours.[255] Enrofloxacin has an elimination $T_{1/2}$ of 4.4 hours after intravenous administration and 10 hours after intramuscular administration, indicating flip-flop kinetics.[251] With oral administration the elimination $T_{1/2}$ of enrofloxacin is 8 hours.[254] After oral administration the elimination $T_{1/2}$ of orbifloxacin is 9 hours and the clearance is 6.3 ml/min/kg in adult mares.[243] Difloxacin has prolonged elimination in the horse, with a $T_{1/2}$ of 18 hours (J. Bertone, unpublished data, 2001).

4.2.16.4 ADVERSE EFFECTS AND DRUG INTERACTIONS

Toxicity of fluoroquinolones is mild in most species and gastrointestinal irritation is the most common side effect.[244] The most clinically concerning effects are arthropathies. Transient arthropathies occur when fluoroquinolones are used to treat *Pseudomonas* pneumonia in children with cystic fibrosis, but the benefits are considered to outweigh the risks.[256] Chronic, high-dose fluoroquinolone therapy causes articular cartilage lesions in juvenile dogs, particularly in weight-bearing joints.[257] No documented arthropathies have been reported for calves, swine, or poultry. An in vitro study using equine cartilage explants did not demonstrate cartilage damage from enrofloxacin, although high doses reduced proteoglycan synthesis.[258] Arthropathies

have been documented in 2-week-old foals after receiving 10 mg/kg of enrofloxacin orally. Damage was characterized by synovial joint effusion and lameness, erosion, and cleft formation in articular cartilage.[259] Arthropathies were not seen in adult horses that were given up to 25 mg/kg of enrofloxacin intravenously 211
daily for 3 weeks or 15 mg/kg orally every 12 hours for 3 weeks.[253,260] Although not recommended for use in 212
pregnant women or animals, the fluoroquinolones appear to have little effect on the developing fetus.[261] Enrofloxacin was used successfully to treat chronic pleuritis in a pregnant mare with no apparent detrimental effects on the foal.[262]

Ciprofloxacin and enrofloxacin interfere with the cytochrome P-450 system metabolism of methylxanthines such as theophylline. Serum theophylline concentrations may double and result in CNS and cardiac toxicity, so one must monitor concentrations during therapy.[263]

The fluoroquinolones may cause adverse CNS effects in human beings and animals because of a γ-aminobutyric acid receptor antagonism, which has been associated with an increase in seizure incidence in human beings and dogs.[244] Administration of enrofloxacin to human beings results in hallucinations. Rapid intravenous administration of high doses of enrofloxacin to horses causes transient neurologic signs, including excitability and seizurelike activity.[260] These signs are avoidable with slow injection or dilution of the dose. Photosensitivity reactions and Achilles' tendon rupture have been associated with fluoroquinolone use in human beings but have not been reported in animals.[244]

The fluoroquinolones have been used with other antimicrobial agents to expand the therapeutic spectrum, to suppress emergence of drug-resistant bacterial populations, or to exploit inhibitory or bactericidal synergism against drug-resistant populations. Minimal synergy occurs between fluoroquinolones and β-lactams or aminoglycosides against gram-negative enteric bacteria because of the already high susceptibility of these organisms. Combinations with aminoglycosides, β-lactams, or vancomycin are additive or indifferent against staphylococci. Antagonism between fluoroquinolones and chloramphenicol or rifampin appears to be caused by the inhibition of bacterial autolysin synthesis from concurrent administration of bacterial protein synthesis inhibitors.[245]

4.2.16.5 FORMULATIONS

Ciprofloxacin is available as human labeled tablets, as a diluted solution for intravenous administration, and as a solution for ophthalmic use. Enrofloxacin is available as oral tablets and a 50 mg/ml injectable solution for intramuscular injection in dogs. In the United States, enrofloxacin is available as 100 mg/ml injectable solution for the subcutaneous treatment of cattle. Both injectable solutions can be administered intravenously to horses. Orbifloxacin and danofloxacin are available as oral tablets for small animals.

4.2.16.6 CLINICAL USE

The use of fluoroquinolones in horses has been limited by fear of inducing arthropathies; however, enrofloxacin has been used successfully in clinical cases, and fluoroquinolones may be the only viable option for treating some infections.[262,264–266] Because the fluoroquinolones are concentration-dependent killers with a long PAE, the ideal dosage regimen is once-daily, high-dose therapy.

4.2.17 Rifampin

4.2.17.1 MECHANISM OF ACTION

The rifamycins are antibiotics produced from *Streptomyces mediterranei*. Rifampin inhibits DNA-dependent RNA polymerase in susceptible organisms, suppressing RNA synthesis. Rifampin has no effect on the mammalian enzyme. Its action is bacteriostatic or bactericidal depending on the susceptibility of the bacteria and the concentration of the drug. Rifampin is effective against a variety of mycobacterium species and *Staphylococcus aureus, Haemophilus*, and *Rhodococcus equi*.[267] Rifampin is considered especially active in staphylococcal and rhodococcal infections and in the eradication of pathogens located in difficult-to-reach target areas, such as inside phagocytic cells. Rifampin is active at an acid pH, making it a rational choice for treating septic foci and granulomatous infections. Rifampin has moderate activity against *Actinobacillus suis, Actinobacillus equuli, Bordetella bronchiseptica*, and *Pasteurella* spp.[267,268] Equine isolates of *Pseudomonas aeruginosa, Escherichia coli, Enterobacter cloacae, Klebsiella pneumoniae, Proteus* spp., and *Salmonella* spp. are resistant.[267] The ability of rifampin to reach intracellular bacteria can make predicting in vivo therapy results difficult based on in vitro sensitivity tests. Bacterial resistance to rifampin develops rapidly; therefore it usually is administered with another antimicrobial.[269] Although rifampin commonly is combined with erythromycin to treat *R. equi*,[239] resistance to the combination has been reported.[221,270] The combination is also effective for treating equine monocytic ehrlichiosis (Potomac horse fever).[241]

4.2.17.2 PHARMACOKINETICS

4.2.17.2.1 Absorption

The oral bioavailability of rifampin varies from 70% in fasted horses to 26% when administered with feed.[30,268,271] Because rifampin is administered most often with feed, recommended dosages compensate for the decreased bioavailability. Bioavailability after intramuscular injection is 60%.[271]

4.2.17.2.2 Distribution

Rifampin is lipophilic and penetrates most tissues, including milk, bone, abscesses, and the CNS. Feces,
saliva, sweat, tears, and urine may be discolored red-orange by rifampin and its metabolites.[272] The Vd of 212
rifampin in horses is 0.6 to 0.9 L/kg.[268,271] Rifampin is 78% bound to plasma proteins.[268] 213

4.2.17.2.3 Elimination

In other species, rifampin is deacetylated hepatically to a metabolite that also has antibacterial activity. Desacetylrifampin was not detected in serum samples after an intravenous dose of 10 mg/kg or oral doses of 10 mg/kg every 12 hours for seven doses.[268] Desacetylrifampin was measured in urine, but rifampin was much more predominant. However, only 6.82% of the total dose was recovered in the urine as rifampin or desacetylrifampin.[268] The elimination $T_{1/2}$ of rifampin is 6 to 8 hours after intravenous administration and 12 to 13 hours after oral administration.[267,268] Because of immature hepatic metabolism, elimination of

rifampin is delayed in very young foals.[273,274] Plasma clearance ranges from 1.14 to 1.34 ml/min/kg.[268,271] As a hepatic enzyme inducer, rifampin induces its own metabolism so that multiple oral dosing significantly decreases the elimination $T_{1/2}$.[268] Enzyme induction typically has not been observed with less than 5 days of therapy, but once it occurs, the increase in enzyme activity may last for more than 2 weeks after discontinuation of treatment.[275]

4.2.17.3 ADVERSE EFFECTS AND DRUG INTERACTIONS

Rifampin stains everything it contacts, and treated animals may produce red urine, tears, sweat and saliva. Discoloration causes no harmful consequences. Most horses object to the taste of rifampin, so one must take care to deposit a dose well back on the tongue and rinse the mouth of the horse afterward. Microsomal enzyme induction from rifampin may shorten the elimination $T_{1/2}$ and decrease plasma drug concentrations of chloramphenicol, corticosteroids, theophylline, itraconazole, ketoconazole, warfarin, and barbiturates.[272]

4.2.17.4 FORMULATIONS

Rifampin is available as human labeled capsules or suspension for oral administration or as a diluted solution for intravenous use.

4.2.17.5 CLINICAL USE

Rifampin is used primarily to treat pulmonary abscess from *R. equi* in foals in combination with erythromycin.

4.2.18 Metronidazole

4.2.18.1 MECHANISM OF ACTION

Bacteria readily take up metronidazole and metabolize it by a reduction process to cytotoxic derivatives (short-lived free radical compounds). These cytotoxic compounds damage DNA and other critical intracellular macromolecules. Aerobic bacteria lack the reductive pathway necessary to produce the radical compounds.[276] Metronidazole is highly effective against anaerobic bacteria, including *Bacteroides fragilis* (penicillin-resistant), *Fusobacterium*, and *Clostridium* spp. Metronidazole also has good activity against protozoa, including *Giardia* and *Trichomonas* spp.[277]

4.2.18.2 PHARMACOKINETICS

4.2.18.2.1 Absorption

Metronidazole is absorbed well and rapidly after oral administration in horses, with an oral bioavailability of 75% to 85%.[277,278] In horses with gastrointestinal ileus, metronidazole may be administered per rectum and is absorbed rapidly; however, the bioavailability is only 30%.[279]

4.2.18.2.2
Distribution

Metronidazole is lipophilic and widely distributed in tissues. Metronidazole penetrates bone, abscesses, and the CNS. The Vd in mares is 0.7 to 1.7L/kg.[277,278]

4.2.18.2.3
Elimination

Metronidazole is metabolized primarily in the liver. Metabolites and unchanged drug are eliminated in urine and feces. Plasma clearance is 2.8 ml/min/kg, and elimination $T_{1/2}$ is 3 to 4 hours in horses.[277–280]

4.2.18.3
ADVERSE EFFECTS AND DRUG INTERACTIONS

In clinical use, metronidazole is associated only with anorexia with oral administration.[281] Metronidazole produces mutations in bacteria, and carcinogenicity occurs in laboratory mice with prolonged exposure. Therefore metronidazole is banned for use in food animals. Metronidazole has been implicated as a teratogen in laboratory animals, so one should avoid using it in pregnant animals.[282]

Because of its limited antimicrobial spectrum, metronidazole is merely additive to aminoglycosides and β-lactams for treating polymicrobial infections.

4.2.18.4
FORMULATIONS

Metronidazole is available only as human labeled formulations and most commonly is administered orally as tablets and capsules. Because metronidazole is poorly soluble, the intravenous formulation must be diluted in a large volume for administration and is expensive in horses.

4.2.18.5
CLINICAL USE

Metronidazole is used to treat anaerobic infections, especially pleuropneumonia and lung abscesses caused by
penicillin-resistant *Bacteroides fragilis* and clostridial enterocolitis.[281,283,284] Although rectal absorption is 213
inferior to oral absorption, rectal administration is a viable option for treatment when oral administration is not 214
feasible.

4.3

4.3—Nonsteroidal Antiinflammatory Drugs

Patricia M. Dowling

220

221

The most commonly used drugs for pain and inflammation in horses are the nonsteroidal antiinflammatory drugs (NSAIDs). The NSAIDs inhibit the enzyme cyclooxygenase, which converts arachidonic acid to the prostaglandins, thromboxane, and prostacyclin (Figure 4.3-1). Blocking these ecosanoids results in antiinflammatory, analgesic, antipyretic, antiendotoxic, and antithrombotic effects.[1]

4.3.1

Mechanism of Action

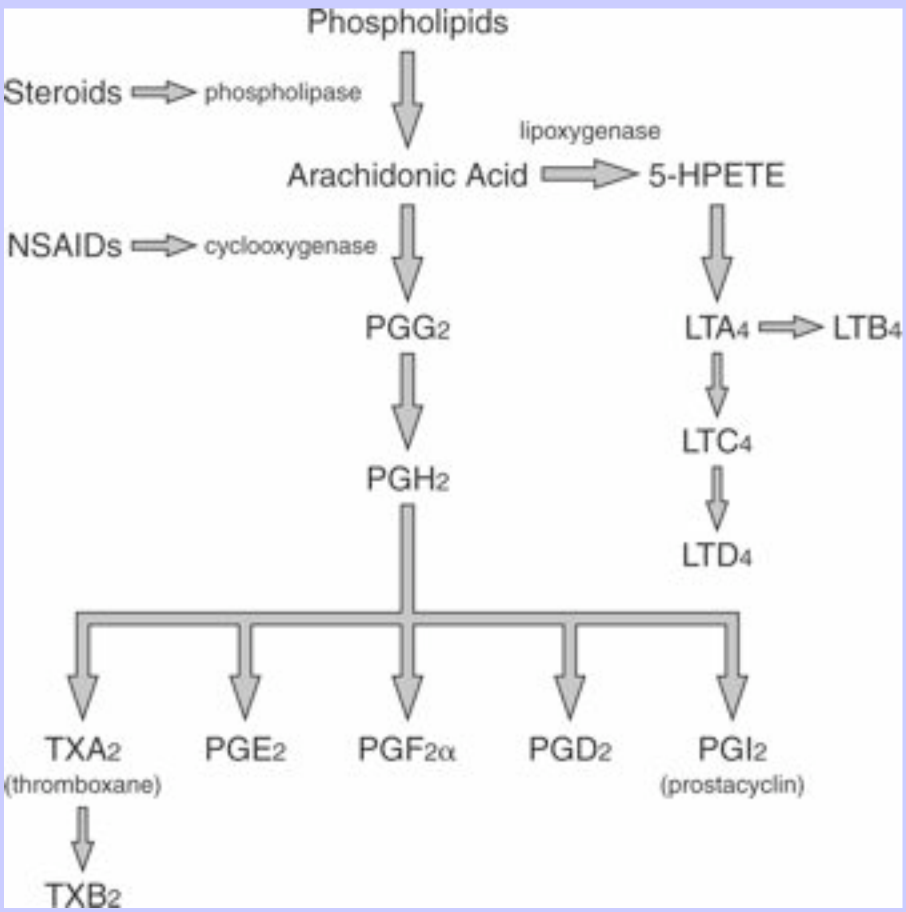
4.3.1.1

CYCLOOXYGENASE INHIBITION

Two different, distinct forms of cyclooxygenase (COX) have been identified. The constitutively expressed form is considered normal for homeostasis and is referred to as *COX-1*, whereas the inducible form in response to injury is considered detrimental and is referred to as *COX-2*.[2] COX-1 is found in platelets, the kidneys, and the gastrointestinal tract. COX-2 is identified in fibroblasts, chondrocytes, endothelial cells, macrophages, and mesangial cells. COX-2 is induced by exposure to various cytokines, mitogens, and endotoxin and is upregulated at inflammation sites.[3] Unfortunately, this classification of “good” versus “bad”

COX is too simplistic to explain the roles of its different forms.[4] COX-2 now appears to be be produced constitutively in the brain, spinal cord, kidney, ovary, uterus, placenta, thymus, bone, cartilage, synovia, endothelia, prostate, and lung. Hormones, nitric oxide, cytokines, and lipoxygenase products also can induce COX-2. COX-2 also is involved in cellular processes including gene expression, differentiation, mitogenesis, apoptosis, bone modelling, wound healing, and neoplasia.[5]

Figure 4.3-1 In the arachidonic acid cascade, cyclooxygenase works on arachidonic acid to produce prostaglandins *(PG)*, thromboxanes *(TX)*, and prostacycline, whereas lipoxygenase works on arachidonic acid to produce leukotrienes *(LT)*. *NSAIDS*, Nonsteroidal antiinflammatory drugs; *HPETE*, hydroperoxyeicosatetraenoic acid.



The prostaglandins produced in the gastrointestinal tract and the kidney that maintain mucosal integrity in the upper gastrointestinal tract and renal perfusion appear to be derived from COX-1.[6] Therefore suppressing COX-1 activity by NSAIDs is believed to be critical to the development of toxicity. One suggestion is that COX-2–selective NSAIDs would suppress prostaglandin synthesis at sites of inflammation but would spare

constitutive prostaglandin synthesis in the gastrointestinal tract and kidney.[3] The currently available NSAIDs vary in their potency as inhibitors of COX-1, but virtually all are far more potent inhibitors of COX-2 than of COX-1.[6] The pharmaceutical companies raced to develop COX-2– selective NSAIDs, but this now appears not to be a perfect solution. If COX-2 is primarily responsible for the prostaglandins that mediate pain, inflammation, and fever, then COX-2–selective drugs are not necessarily more therapeutically effective, because the nonselective NSAIDs are already effective inhibitors of COX-2.[5] Moreover, COX-1–derived prostaglandins now have been shown to contribute to pain, inflammation, and fever, so COX-2–selective NSAIDs actually may be less effective.[5,7] Studies are published now showing that some COX-2– selective drugs are only therapeutically effective at doses high enough to inhibit COX-1.[7] Also, COX-2 may produce beneficial prostaglandins; therefore highly selective COX-2 inhibitors may produce adverse reactions not seen with existing NSAIDs.[6] Most gastrointestinal ulceration also is associated with significant mucosal inflammation. In these circumstances, COX-2 likely is expressed and the derived prostaglandins are responsible for promoting healing.[8] NSAIDs are well known to retard the healing of ulcers and exacerbate inflammatory bowel disease.[6]

4.3.1.2

ANTIINFLAMMATORY EFFECTS

The NSAIDs are primarily antiinflammatory because of their inhibition of prostaglandin production. Therefore NSAIDs do not resolve inflammation but prevent its ongoing occurrence. So while prostaglandin production rapidly diminishes, any previously present prostaglandin must be removed before inflammation subsides. From tissue cage work, phenylbutazone, ketoprofen, and carprofen have been shown to have delayed peak concentrations at the site of inflammation and persist in inflammatory exudates for long periods after plasma concentrations are negligible.[9–11] This action explains the delayed onset and prolonged duration of antiinflammatory action that does not correlate with plasma pharmacokinetics of the NSAIDs.

The NSAIDs commonly are used in horses to attenuate the prostaglandin-mediated effects of endotoxin.[12,13] 221
Low-dose flunixin has antiendotoxin effects without obscuring the signs of colic pain or causing toxicity but 222
does not alter endotoxin-induced leukopenia.[14–19] A combination of flunixin and pentoxifylline may offset the deleterious hemodynamic effects of endotoxin more effectively than either drug alone.[20] Flunixin and phenylbutazone significantly inhibit movement of polymorphonuclear and mononuclear cells and antagonize the effects of endotoxin on bowel motility.[12,21]

4.3.1.3

OTHER ANTIINFLAMMATORY EFFECTS

COX inhibition does not explain all of the antiinflammatory activity of NSAIDs. NSAIDs are more lipophilic at a low pH, such as is found in inflamed tissues. Some antiinflammatory action appears to be related to their ability to insert into the lipid bilayer of cells and disrupt normal signals and protein-protein interactions in cell membranes. In the cell membrane of neutrophils, NSAIDs inhibit neutrophil aggregation, decrease enzyme release and superoxide generation, and inhibit lipoxygenase.[22]

4.3.1.4

ANALGESIC EFFECTS

The NSAIDs act as analgesics by inhibiting COX and preventing the production of prostaglandins that sensitize the afferent nociceptors at peripheral sites of inflammation.[23] However, increasing evidence indicates

that some NSAIDs have a central mechanism of action at the level of the spinal cord for analgesia unrelated to COX inhibition.[24] This action is synergistic with opioids and α_2-adrenergic drugs.[24,25] Work with the specific enantiomers of some NSAIDs have shown the S enantiomers to have good COX inhibitory effects, whereas the R forms can have weak activity against COX yet still produce analgesia.[26,27]

4.3.1.5 CLINICAL IMPLICATIONS

Therefore for managing pain and inflammation in horses, NSAIDs are more effective as analgesics when inflammation is a part of the pain process and when they are given before the onset of the inflammatory process or insult. The time to onset and duration of analgesia of NSAIDs does not correlate well with their antiinflammatory properties. The analgesic effect has a more rapid onset and shorter duration of action than the antiinflammatory action, so that dosage regimens for effective analgesia may need to be different from those for antiinflammatory effects.[23]

4.3.1.6 EFFECTS ON CARTILAGE

One should consider the effects of NSAIDs on proteoglycan synthesis in their clinical use for equine joint disease. Many NSAIDs affect cartilage anabolism in addition to their antiinflammatory actions.[28] Salicylates produce profound suppression of proteoglycan synthesis in osteoarthritic cartilage compared with normal cartilage.[29] A few NSAIDs, such as carprofen and meloxicam, have been shown to increase proteoglycan synthesis.[26,29,30] Phenylbutazone does not affect proteoglycan synthesis or chondrocyte viability but is protective against chondrocyte-mediated catabolism.[28]

4.3.2 Chirality

Many of the NSAIDs are *stereoisomers*, which consist of enantiomers with the same molecular formula, but because of asymmetrically oriented chemical groups on a central carbon, they form three-dimensional, nonsuperimposable mirror images and are known as *chiral* compounds.[31] This means that they are like one's hands: superimposable palm to palm, but not palm to back. For the NSAIDs the S (sinister) and R (rectus) designations for each of a pair of enantiomers commonly are used.[32] Although each member of a pair of enantiomers differs in three-dimensional orientation, its physical properties (e.g., melting and boiling points, refractive index, and solubility) are identical.[31] Biologic systems are highly chiral environments, and the pharmacokinetics and pharmacodynamic effects of each of a pair of enantiomers may be different. Stereospecificity may occur in the pharmacokinetic processes of absorption, distribution, metabolism, and excretion, especially if the process involves a carrier protein. If the fit of a drug molecule into the binding site on a protein, enzyme, or receptor involves the chiral center, then the affinity for attachment will be different for each of a pair of enantiomers.[33] Therapeutic efficacy and toxicity may be related specifically to one enantiomer. For the chiral NSAIDs, the S enantiomer typically is associated with COX inhibition, and the R enantiomer is associated with analgesic effects. Most chiral drugs are formulated as racemic mixtures, containing equal amounts of each enantiomer, for pure enantiomeric compounds are difficult and expensive to manufacture. All of the propionic acid NSAIDs (ketoprofen, carprofen, vedaprofen, and naproxen) are chiral compounds, and except for naproxen they are formulated as racemic mixtures. After administration, some enantiomers undergo *chiral inversion* as hepatic enzymes convert one form of the enantiomer to the other form. The chiral inversion of propionic acid derivatives is almost invariably unidirectional from R to S.[31] The degree of chiral inversion varies

between species and cannot be predicted from one species to another, making extrapolating dosages for NSAIDs from one species to another hazardous.

4.3.3 Physical Properties

Almost all NSAIDs are weak acids and highly bound to plasma proteins such as albumin. Therefore they are 222
well absorbed from the stomach, and most of the drug in the plasma is protein bound. Because of protein 223
binding, they are distributed predominantly in the extracellular fluid, and only low concentrations of NSAIDs are found in normal tissues and joint fluid. In damaged tissues and joints, however, NSAID concentrations increase to therapeutic levels because of increased blood flow, vascular permeability, and acute phase protein penetration into sites of inflammation. Most NSAIDs undergo hepatic metabolism through oxidation or glucuronide conjugation before being eliminated in the urine.[1]

4.3.4 Drug Interactions

One must consider the occurrence and potential hazards of drug interactions with therapeutic use of the NSAIDs. In general, any two NSAIDs administered together are additive in their effect.[34,35] Because most NSAIDs act by similar mechanisms of COX inhibition, a higher dose of a single NSAID should produce the same response. Because all of the NSAID drugs are highly bound to plasma proteins, one must use caution when administering other highly protein-bound drugs such as warfarin (coumarin).[34,36,37] Competition for protein binding sites can result in dramatic increases in free drug available for pharmacologic action. Antacids, mucoprotective agents, and adsorbent antidiarrheal drugs can interfere with NSAID absorption.[34] Concurrent use of corticosteroids potentiates gastrointestinal ulceration.[38] Chloramphenicol decreases the elimination rate, and rifampin significantly increases the elimination rate of phenylbutazone.[39] Concurrent administration of phenylbutazone and procaine penicillin G results in higher serum concentrations of penicillin because of decreased tissue distribution.[40] Concurrent administration of gentamicin and phenylbutazone results in increased distribution and delayed elimination of gentamicin.[41] Phenylbutazone decreases urinary excretion of furosemide and attenuates furosemide-induced increases in urinary excretion of sodium and chloride.[42]

4.3.5 Adverse Effects of NSAIDs

The adverse effects of the NSAIDs are related to COX inhibition in tissues where prostaglandins are beneficial and protective. Platelet aggregation classically is inhibited by NSAIDs by preventing thromboxane production via the COX-1 pathway.[1] Recovery of platelet function depends on the pharmacokinetics of the NSAID and the mechanism of COX inhibition.[43–46] Aspirin permanently modifies COX, so platelet function is restored only by the production of new platelets.[43,47] Reducing the protective prostaglandins results in blood vessel constriction and tissue necrosis in the kidney and reduction in blood flow and protective mucus production in the gastrointestinal tract.[6] Renal papillary necrosis (medullary crest necrosis), oral and gastrointestinal ulceration, and right dorsal colitis have been associated with NSAID use in the horse.[48–56] The NSAIDs have a higher incidence of toxicity in neonates because kidney and liver function is not developed fully.[55,57–59] When indicated in neonates, one should administer NSAIDs at the lowest possible doses and at extended dosing intervals. One should administer NSAIDs cautiously to dehydrated animals.[48,49] Because NSAIDs predominately distribute in extracellular water, plasma concentrations are greater than normal in the dehydrated animal and are more likely to cause toxicity.

Treatment of NSAID gastrointestinal toxicity is intensive and mainly symptomatic.[50] One can correct the hypoproteinemia that results from loss of plasma proteins into the ulcerated gastrointestinal tract with intravenous infusions of plasma. One can manage the fluid and electrolyte losses that accompany the diarrhea with commercially available intravenous fluids. Broad-spectrum antibiotics are indicated for bacterial septicemia. One must manage pain with opioid analgesics. Antiulcer medications may be beneficial and speed recovery. Surgical removal of damaged sections of stomach or colon may be necessary in some cases.[50] Recovery is usually slow, and in severe cases the prognosis is always guarded.

The renal toxicity of NSAIDs is a major concern, particularly in the perioperative period. NSAIDs typically have little effect on renal function in normal adult animals.[60] However, NSAIDs decrease renal blood flow and glomerular filtration rate in patients that have congestive heart failure, are hypotensive or hypovolemic (especially during anesthesia and surgery), or have chronic renal disease.[22] Under these circumstances, NSAIDs may precipitate acute renal failure as they block the ability of renal prostaglandins to mitigate the vasoconstrictive effects of norepinephrine and angiotensin II on glomerular arteries. COX-2–selective drugs do not seem to avoid this problem.[61] A more severe dose-dependent toxicity associated most commonly with phenylbutazone is renal papillary necrosis.[48,55,56] Although attributed to impaired renal blood flow, other mechanisms such as direct nephrotoxicity of the drug or its metabolites also may be involved.

4.3.6 Aspirin

Aspirin (sodium salicylate) is only available in oral forms. Because aspirin is a weak acid, it is best absorbed in the acidic environment of the upper gastrointestinal tract. During absorption, aspirin is hydrolyzed partially to salicylic acid and distributed throughout the body. The highest concentrations are attained in the liver, heart,
lungs, renal cortex, and plasma. The extent of protein binding is moderate (about 60%) and depends on species 223
and drug and albumin concentrations. Aspirin is metabolized hepatically by glycine and glucuronide 224
conjugation. Salicylates and their metabolites are excreted rapidly in urine via glomerular filtration and active tubular excretion, with an elimination half-life in the horse of approximately 1 hour.[1] In the horse, salicylic acid is the primary salicyl compound found in urine.[62] Significant tubular reabsorption occurs, which depends greatly on pH.[1]

Aspirin is the most effective NSAID for antiplatelet therapy.[43,63,64] Aspirin irreversibly acetylates the COX present in platelets, which inhibits the formation of thromboxane A_2, which is responsible for vasoconstriction and platelet aggregation.[43,46,47,64,65] Antiplatelet therapy may be beneficial for managing equine laminitis, disseminated intravascular coagulation, and equine verminous arteritis. A precise antiplatelet dose has not been established, but a dose of 12 mg/kg prolongs bleeding time for 48 hours.[43]

4.3.7 Carprofen

Carprofen is a propionic acid derivative formulated as a racemic mixture. Carprofen is currently available for use in horses in Europe, and its approval is being sought for use in North America. The volume of distribution (Vd) is 0.1 L/kg for the R enantiomer and 0.29 L/kg for the S enantiomer. At the recommended dose of 0.7 mg/kg, carprofen has a longer elimination half-life in horses than most other NSAIDs. After intravenous administration the plasma elimination half-life is 21 hours for the R enantiomer and 17 hours for the S enantiomer.[9] The R enantiomer predominates in plasma and exudates because of hepatic stereospecificity for glucuronidation of the

S enantiomer, leading to its more rapid clearance. Chiral inversion of carprofen does not occur in the horse.[66] Like other NSAIDs, carprofen accumulates in inflammatory exudate but produces only modest reductions in the concentrations of ecosanoids compared with flunixin or phenylbutazone.[9,67] Despite this, carprofen produces significant analgesia, likely because of central actions of the R enantiomer.[30]

4.3.8 Flunixin Meglumine

Flunixin meglumine is a potent inhibitor of COX that is approved for use in horses and is available in injectable and oral formulations. Flunixin is absorbed rapidly following oral administration, with a bioavailability of 86% and peak serum levels within 30 minutes.[68] Feeding delays absorption.[69] The Vd is 0.1 to 0.3 L/kg in horses, and the plasma elimination half-life is 1 to 2 hours.[68,70,71] In newborn foals the elimination half-life is prolonged at 13.4 hours. The Vd also increases in the newborn foal, as is expected with a low-Vd drug in the neonate.[72] Flunixin is highly protein bound (86%) but appears to partition into tissues readily, hence the high volume of distribution.[73,74] The elimination half-life in inflammatory exudate is 16 hours.[75] The onset of antiinflammatory action is within 2 hours, peak response occurs between 12 and 16 hours, and duration of action is 36 hours. Analgesic effects have a more rapid onset and shorter duration. Only 14% of a dose is excreted in urine, but otherwise little is known about the metabolism of flunixin.[1]

Flunixin is used in horses for a variety of inflammatory and painful conditions including colic, colitis, exertional rhabdomyolysis, endotoxic shock, respiratory disease, ocular disease, general surgery, and laminitis.[1] Flunixin is more effective at preventing the clinical signs of endotoxemia than phenylbutazone but appears equivalent to ketoprofen.[76] Flunixin may prevent abortion in endotoxic mares.[77] The label dose is 1.1 mg/kg every 12 hours, whereas low-dose therapy at 0.25 mg/kg every 8 hours inhibits the cardiovascular effects of endotoxemia. Extremely high doses of flunixin may mask signs of surgical colic pain and interfere with treatment decisions.

Flunixin has a good safety profile, but high doses or chronic dosing can cause anorexia, depression, and gastrointestinal ulcers.[53,78] In normal foals the label dose of flunixin administered for 5 days did not produce adverse effects, but 6 times the label dose resulted in gastrointestinal ulcers.[59] In another study, foals were administered flunixin at the label dose for 30 days and all treated foals developed gastric ulcers.[57] Intramuscular injections of flunixin greatly irritate muscle and have been incriminated in cases of clostridial myositis in horses and so should be avoided when possible despite the label directions.[79,80]

4.3.9 Ketoprofen

Ketoprofen is a chiral propionic acid derivative approved for horses as a racemic solution for intravenous or intramuscular injection. Oral and rectal bioavailability is too poor for these routes to be used clinically.[81–83] Ketoprofen is 92.8% protein bound in horses.[84] Ketoprofen has a moderate Vd for both enantiomers of approximately 0.5 L/kg and short plasma elimination half-lives of 1 to 1.5 hours.[11,27,75,83,84] Ketoprofen is metabolized hepatically by conjugation reactions, with only 25% of a dose eliminated as unchanged drug in urine.[84] The S enantiomer is associated with antiprostaglandin activity and toxicity, whereas the R enantiomer is associated with analgesia and does not produce gastrointestinal ulceration.[11,85] Because of chiral inversion the S enantiomer predominates in horses.[11] Ketoprofen accumulates in inflammatory exudates in the horse, where the elimination half-life of the S enantiomer is 23 hours and of the R enantiomer is 20 hours. The maximum 224

antiinflammatory effects of ketoprofen occur at 4 hours after a dose and last for 24 hours, illustrating that the antiinflammatory effects are not related to plasma concentrations.[75]

In studies of noninfectious arthritis, endotoxemia, and colic, ketoprofen is clinically similar to flunixin meglumine in efficacy.[75,76,85] In an experimentally induced synovitis model, phenylbutazone was more effective in reducing lameness and synovial fluid prostaglandin concentrations.[86] In horses with chronic laminitis, ketoprofen was more effective than phenylbutazone at relieving pain, but only at a higher-than-label dose.[87] In a comparative toxicity study, ketoprofen at the label dose had less potential for toxicity than flunixin meglumine or phenylbutazone.[53] In drug tolerance studies using 25 times the label dose for 5 days, horses developed depression, icterus, nephritis, hepatitis, and hemorrhagic necrosis of the adrenal glands.[88]

4.3.10 Meclofenamic Acid

Meclofenamic acid is an oral granule used in horses for treating musculoskeletal conditions. The drug is older and has not been researched extensively in veterinary medicine. The plasma elimination half-life in horses ranges from 1 to 1.4 hours after intravenous administration but increases to 2.6 hours with oral administration because of flip-flop kinetics.[89,90] Meclofenamic acid is highly protein bound (98.9%).[74] Therapeutic efficacy does not correlate well with plasma concentrations because the onset of clinical action is 36 to 96 hours after administration, and significant efficacy can be seen for days following a dose.[91] The dose is 2.2 mg/kg orally every 24 hours. Feeding before dosing may delay absorption of meclofenamic acid.[92] Repeated daily dosing does not result in drug accumulation; therefore drug is useful for chronic inflammatory conditions.[91]

Many horses can be maintained comfortably with twice weekly dosing without side effects. In clinical studies, researchers found clinical improvement in the lameness of two thirds of treated horses but found predicting which horses would respond to meclofenamic acid to be difficult.[91] At normal doses, some decrease in plasma protein concentration may occur. Doses of 6 to 8 times the label dose result in toxicity, including mouth ulcers, anorexia, depression, edema, and weight loss. Chronic administration at the label dose to stallions and pregnant mares caused no toxic effects.[93]

4.3.11 Phenylbutazone

Phenylbutazone is the most widely used NSAID in the horse and is available in many generic intravenous and oral formulations. Following oral administration, phenylbutazone is well absorbed; however, feeding may delay time to peak concentration.[92,94–96] The Vd is 0.15 L/kg, with highest concentrations in the liver, heart, kidney, lungs, and plasma.[96] The elimination half-life is 3.5 to 7 hours.[97] In neonatal foals the Vd is higher (0.27 L/kg) and the elimination half-life is longer (6.4 to 22.1 hours) than in adult horses.[98] Plasma protein binding in horses is greater than 99%.[97] The liver metabolizes phenylbutazone to oxyphenbutazone, an active metabolite that is eliminated more slowly from the body than phenylbutazone. Oxyphenbutazone inhibits the metabolism of phenylbutazone.[99] Phenylbutazone and its metabolite cross the placenta and are excreted in milk. Less than 2% is excreted in the urine as unchanged drug. The capacity of the liver to metabolize phenylbutazone becomes overwhelmed at low drug doses, resulting in dose-dependent kinetics.[97] The elimination half-life increases with increasing dose rates and increasing age.[93,97,100] The elimination half-life from exudate is 24 hours.[10] Therapeutic efficacy lasts for more than 24 hours because of irreversible binding of phenylbutazone to COX, slow elimination from inflamed tissues, and long elimination half-life of oxyphenbutazone.[97] Therefore high or

frequent doses of phenylbutazone result in disproportionately increasing plasma concentrations, which easily result in toxicity.

Phenylbutazone is used extensively in horses for a variety of musculoskeletal disorders.[25] Phenylbutazone may be useful for acute colic cases, antagonizing the disruptive effects of endotoxin on bowel motility without entirely blocking the cardiovascular effects that indicate a surgical lesion.[12] Phenylbutazone appears to inhibit prostaglandin synthesis at low plasma concentrations in the horse (5 to 15 μg/ml), whereas in human beings inhibition requires much higher drug concentrations (50 to 150 μg/ml).[97] This effect probably is due to a species difference in the structure of COX. An initial dose of 4.4 mg/kg every 12 hours the first day of therapy is followed by a decreased dose and increased dosing interval for subsequent therapy. Because of accumulation from the long elimination half-life of phenylbutazone and oxyphenbutazone, chronic therapy should be at least every other day.

Phenylbutazone has a narrow safety margin, especially in foals, ponies, and dehydrated horses.[48,58] Phenylbutazone toxicity most commonly results in gastrointestinal effects, including oral, esophageal, gastric, cecal, and right dorsal colonic ulcerations and accompanying protein-losing enteropathy, hypoproteinemia, leukopenia, and anemia.[48–52,101] Renal papillary necrosis (renal medullary crest necrosis) occurs because of inhibition of prostaglandins that maintain renal blood flow and direct toxicity of phenylbutazone and metabolites.[56] Because phenylbutazone can mask signs of lameness in horses for several days following therapy, 225
one may use it to disguise lameness for the purpose of soundness examinations or for competition.[97] 226
Phenylbutazone may interact with other highly protein bound drugs such as warfarin (coumarin).[97] Extravascular administration results in severe tissue necrosis. Phenylbutazone may decrease bone healing in fractures.[102] Phenylbutazone significantly suppresses total thyroxine and free thyroxine concentrations in horses for 10 days.[103]

4.3.12 Vedaprofen

Vedaprofen is related structurally to ketoprofen and carprofen and also is formulated as a racemic mixture of S and R enantiomers. Vedaprofen is available as a palatable gel for oral administration with a loading dose of 2 mg/kg followed by 1 mg/kg every 12 hours. Oral bioavailability is approximately 100%, and vedaprofen is highly protein bound (99%). Within 2 hours after intravenous administration, the mean R:S plasma concentration ratio is 95:5, which results from significant distribution and elimination differences between the enantiomers and not from chiral inversion. The R enantiomer has an elimination half-life of 2.2 hours and a Vd of 0.23 L/kg, whereas the S enantiomer has an elimination half-life of 0.76 hours and a Vd of 0.5 L/kg. Both enantiomers accumulate in inflammatory exudate and are cleared more slowly from exudate than from plasma. In an equine acute nonimmune inflammation model, vedaprofen produced significant inhibition of inflammatory swelling and partially inhibited leukocyte migration into the exudate.[104] Inhibition of leukocyte migration was not seen in this model with other NSAIDs.

4.4 4.4—Respiratory Pharmacology

Patricia M. Dowling

Dogs, cats, horses, and human beings develop spontaneous bronchoconstriction associated with airway inflammation and characterized by chronic cough and wheeze. Effective therapy of inflammatory airway disease is species-dependent because of the inflammatory mediators involved in bronchoconstriction. In the horse, two clinical syndromes are described. Recurrent airway obstruction (RAO) or heaves is an inflammatory, obstructive airway disease clinically evident in middle-aged horses. Exposure of susceptible animals to antigens (typically hay dust, molds, and pollens) induces attacks of airway obstruction. Inflammatory airway disease (IAD) is a low-grade 228
inflammation of the small airways that is a common cause of poor performance in young to middle-aged athletic 229
horses. The goals of therapy for RAO and IAD are to prevent recurrent exacerbations of bronchoconstriction and dyspnea and to avoid emergency veterinary visits; to provide optimal chronic antiinflammatory therapy with minimal or no adverse effects; to maintain (near) normal pulmonary function; and to meet the clients' expectations of quality of life for their horses. Traditional therapy includes the systemic administration of bronchodilators and antiinflammatory drugs. Recently, methods of local delivery of aerosol medications have been developed for horses. Nebulizers, metered-dose inhalers (MDIs), and dry powder inhalers have been adapted for use in horses, with MDIs being the most versatile method of drug delivery. Inhalation therapy delivers high drug concentrations directly to the lungs, avoiding or minimizing systemic side effects. The onset of action for inhaled bronchodilators and antiinflammatory drugs is substantially shorter than that of oral or parenteral formulations. In the United States, MDIs are labeled according to the amount of drug delivered at the valve, whereas in Canada, they are labeled according to the amount of drug delivered to the mouthpiece of the actuator. Despite being ideal for therapy of RAO and IAD, the use of inhaled medications in performance horses is currently controversial, and little is known regarding their potential for causing drug rule violations.

4.4.1 Bronchodilators

The primary innervation of the equine respiratory tract is from the parasympathetic system, which reaches the lung via the vagus nerve. When the parasympathetic nerves release acetylcholine, it binds to M3-muscarinic receptors on airway smooth muscle, releasing calcium from intracellular stores to cause smooth muscle contraction and bronchospasm. α_2-Inhibitory and β_2-excitatory adrenoceptors modulate cholinergic nerves in the airways.[1] In acute bouts of RAO or IAD, histamine, leukotriene D_4, and serotonin contribute to increased

cholinergic airway tone.[2] Stimulation of the β_2-adrenergic receptors leads to increased activity of the enzyme adenylate cyclase, increased cyclic adenosine monophosphate, and relaxation of bronchial smooth muscle.[3]

4.4.1.1 β_2-ADRENERGIC AGONISTS

The β_2-adrenergic agonists have beneficial effects in the treatment of bronchoconstrictive respiratory tract diseases but always should be used with antiinflammatory drugs to treat inflammatory respiratory disease.[4] The β_2-agonists currently used as bronchodilators are racemic mixtures of R and S enantiomers, and their action is stereospecific.[5] In the horse the R enantiomers augment acetylcholine release yet still potently inhibit tracheal smooth muscle contraction. In contrast, the S enantiomers facilitate acetylcholine release but do not inhibit tracheal smooth muscle contraction and therefore do not contribute to the observed bronchodilatory effect. Stimulation of β-receptors on mast cells decreases the release of inflammatory mediators from mast cells but does not suppress other inflammatory cells.[6,7] The β_2-adrenergic receptor agonists also increase mucociliary clearance in the respiratory tract.[8–10] Chronic use of β_2-adrenergic agonists may lead to down regulation of β_2-adrenergic receptors and decreased clinical efficacy.[11]

Epinephrine (adrenaline) is a nonspecific adrenergic agonist; it stimulates α- and β-receptors, producing pronounced vasopressive and cardiac effects in addition to bronchodilation.[1,12,13] Epinephrine is reserved for emergency treatment of life-threatening bronchoconstriction (anaphylaxis). The nonspecific stimulation of other receptors and short duration of action make it unsuitable for long-term use. A 1 mg/ml solution is available, and the dose is 0.005 to 0.01 mg/kg intravenously or 0.02 mg/kg intramuscularly or subcutaneously.

Isoproterenol is a potent β-receptor agonist that causes bronchodilation in horses.[14] Isoproterenol is selective for β-receptors, but the cardiac (β_1) effects make it unsuitable for long-term use. The drug has been administered by inhalation or injection and also has a short duration of action (<1 hour). For emergency relief in horses, isoproterenol is given by slow intravenous injection at a dilution of 0.2 mg/50 ml of saline. Administration is discontinued when the heart rate doubles.[15]

Terbutaline is similar to isoproterenol in its β_2 activity.[16,17] Oral bioavailability in horses is less than 1%, and a short plasma elimination half-life indicates terbulatine should be given as an intravenous infusion to maintain therapeutic concentrations, but adverse cardiac and central nervous system effects may occur.[18]

Albuterol (salbutamol) is similar to isoproterenol.[14] Albuterol is administered to horses most commonly via MDI and is now available as a specific equine device for inhalation therapy (Torpex, 3M and Boehringer Ingelheim Vetmedica).[19] When dosed at 360 or 720 μg in horses with RAO, the onset of action is rapid (5 minutes), and bronchodilation lasts from 30 minutes to 3 hours.[20] The equine product is dosed at 360 μg (3 actuations) every 6 hours. Transient sweating, muscle tremors, or excitement may occur following dosing. *Pirbuterol* and *fenoterol* also have been administered to horses with RAO via metered dose inhalers with similar efficacy.[21–23]

Salmeterol is a long-acting β_2-agonist available in an MDI. Its onset of action is slow (15 to 30 minutes), but 229
its duration of action is long (6 hours).[24] Salmeterol is not recommended for use in an acute attack, but it 230

improves symptom control when used daily in addition to corticosteroids more than just increasing the corticosteroid dose.[25] Salmeterol is dosed at 125 µg (5 actuations) every 12 hours.[26]

Clenbuterol commonly is used orally to treat RAO or IAD in horses. Clenbuterol is available in injectable and oral formulations in Canada, whereas only the oral formulation is available in the United States. Clenbuterol has a lower binding affinity to the β_2-adrenoceptors compared with salbutamol and terbutaline, and efficacy studies have produced conflicting results.[9,17,27,28] Clenbuterol has a significant effect on increasing mucociliary transport in horses with RAO.[8,10] The initial oral dose is 0.8 µg/kg orally every 12 hours. If no response is seen after 3 days, one should increase the dose by 0.8 µg/kg every 3 days. If no response is seen at 3.2 µg/kg, the horse can be considered to have irreversible bronchospasm. Despite being fairly specific for β_2-receptors, the most common adverse effects are tachycardia and muscle tremors.[27] At therapeutic doses in horses, chronic clenbuterol administration is a repartitioning agent, increasing muscle mass while decreasing body fat,[29] and may have a negative effect on cardiac function.[30] Human intoxication has occurred after ingestion of products from food animals treated with clenbuterol, so the drug is banned for use in any animal destined for human consumption.[31]

4.4.1.2 METHYLXANTHINES

The methylxanthines include theophylline, theobromine, and caffeine. Theophylline and the theophylline salt aminophylline have been used as bronchodilators in horses.[32,33] Once the mainstay of human asthma therapy, theophylline has a high incidence of side effects, and its use has diminished with the development of other drugs. The methylxanthines inhibit phosphodiesterase, which increases intracellular cyclic adenosine monophosphate.[34] However, antagonism of adenosine currently is thought to be the most important action for bronchodilation. Adenosine induces bronchoconstriction in asthmatic patients and antagonizes adenylate cyclase. Adenylate cyclase is responsible for the synthesis of cyclic adenosine monophosphate, which is important for bronchial smooth muscle relaxation and inhibition of the release of inflammatory mediators from mast cells.[28,35] Methylxanthines also inhibit prostaglandins, augment the release of catecholamines from storage granules, increase calcium availability to contractile proteins of the heart and diaphragm, and interfere with mobilization of calcium in smooth muscle cells.[36]

Theophylline is available in several formulations, including injectable, aqueous solutions; elixirs; tablets; capsules; and sustained-release formulations. Theophylline is poorly soluble in water and often produces gastrointestinal irritation when administered orally. Aminophylline is a theophylline salt that is 78% to 86% theophylline, is more water soluble, and produces less gastrointestinal irritation. Other theophylline salts are available, and one must consider their theophylline content when developing a drug dosage regimen.

The pharmacokinetics of theophylline and aminophylline have been described in horses.[32,37–41] These drugs are absorbed almost completely after oral administration. Aminophylline is recommended to be dosed orally at 5 mg/kg every 12 hours.[37] An oral loading dose of 20 mg/kg of a sustained-release formulation followed by maintenance doses of 15 mg/kg every 24 hours achieves trough-peak theophylline plasma concentrations between 6 and 17 µg/ml.[39] Ideal therapy requires therapeutic drug monitoring; otherwise, adverse effects such as agitation and tachycardia can occur. These effects and the need for clients to administer numerous tablets or capsules twice daily make chronic therapy with theophylline impractical.

4.4.1.3 ANTICHOLINERGIC DRUGS

The anticholinergic (parasympatholytic) drugs are effective bronchodilators by inhibiting vagally mediated cholinergic smooth muscle tone in the respiratory tract. Asthmatic individuals appear to have excessive stimulation of cholinergic receptors.[42]

Atropine is used for acute bronchodilation in horses, in which a low intravenous dose (0.01 mg/kg) is more effective and less toxic than intravenous aminophylline.[43] A test dose of 5 to 7 mg has been advocated to determine prognosis in horses affected by RAO, with the implication that horses that fail to improve are unlikely to be managed successfully with bronchodilators.[3] Recently, the response to atropine of horses affected by RAO was shown to underestimate improvement in respiratory tract function that results from maintenance on pasture.[44] Atropine is not used for chronic bronchodilation because low doses and even ocular application may cause tachycardia, ileus, neurologic derangement, and blurred vision in horses.[45–48]

Glycopyrrolate is twice as potent as atropine in human beings and does not cross the blood-brain barrier. Information about the use of this drug in horses is sparse, but doses of 2 to 3 mg have been suggested for intramuscular administration.[49]

Ipratropium bromide is a quaternary derivative of atropine that lacks the adverse side effects of atropine and is available in an MDI alone and in combination with albuterol (salbutamol). In asthmatic human beings, ipratropium bromide is used as an additional medication to reverse bronchoconstriction when inhaled short acting β_2-agonists do not give enough relief.[50] The anticholinergic action of ipratropium bromide also 230
decreases mucous secretions. Ipratropium has shown efficacy in horses with RAO.[51–54] The suggested dose is 231
270 μg (15 actuations) every 6 hours.[26]

4.4.2 Glucocorticoids

Glucocorticoids are the mainstay of therapy for inflammatory airway diseases in human beings and animals. They attenuate the inflammatory response, suppressing the generation of cytokines and recruitment of airway eosinophils and release of inflammatory mediators. Glucocorticoids reduce severity of symptoms, improve peak expiratory flow, diminish airway hyperresponsiveness, prevent exacerbations, and possibly prevent airway wall remodelling.[55]

For acute exacerbations of RAO or IAD, parenterally administered glucocorticoids traditionally have been recommended.[3] The most commonly administered drugs are dexamethasone (20 mg intravenously or intramuscularly), isoflupredone acetate (5 to 20 mg intramuscularly), flumethasone (0.04 to 0.15 mg/kg intravenously or intramuscularly), and triamcinolone acetonide (0.022 to 0.044 mg/kg intramuscularly or subcutaneously).[3,49,56]

Based on efficacy in treating human asthma, availability, and low cost, oral prednisone was used commonly for chronic treatment of RAO and IAD.[3,15] Prednisone is a prodrug and in most species is metabolized hepatically to the active drug prednisolone. The efficacy of oral prednisone was questioned,[57–59] and a recent study demonstrated that oral absorption of prednisone is poor and hepatic metabolism to the active drug prednisolone does not appear to occur in horses. Oral prednisolone is effective for treating RAO and IAD,[60] but convenient-

sized tablets are currently unavailable. Oral dexamethasone is available as an equine formulation and is efficacious for chronic therapy in horses.[49]

Systemic administration of glucocorticoids to horses is associated with potentially severe adverse effects. Glucocorticoid administration always has the potential to suppress endogenous production of cortisol. The horse appears to be sensitive to suppression of endogenous cortisol production.[61] The likelihood and degree of suppression increases with duration of action of the corticosteroid.[62] The immunosuppressive effects of corticosteroids are related to dose, steroid potency, and dose interval and can predispose treated horse to infectious disease. Laminitis is associated with dexamethasone and triamcinolone administration in horses.[62,63]

Inhaled corticosteroids are the most potent inhaled antiinflammatory drugs currently available. In human beings, early intervention with inhaled corticosteroids improves asthma control and normalizes lung function and may prevent irreversible airway damage. The potential but small risk of adverse side effects is well balanced by their efficacy. Oral candidiasis (thrush), dysphonia, and reflex cough and bronchospasm are the most common adverse effects in human beings; the use of a spacer reduces all of these effects.[55] Glucocorticoid formulations in MDIs include fluticasone, beclomethasone, budesonide, flunisolide, and triamcinolone. Fluticasone and beclomethasone have shown efficacy in horses with RAO.[64–67] Fluticasone is considered the most potent and longest-acting inhaled glucocorticoid available.[3] Fluticasone doses of 1980 μg (9 actuations) every 12 hours have been recommended.[26] At the currently recommended dose (500 μg every 12 hours), inhaled beclomethasone suppresses adrenocortical function in horses, but use is not associated with clinically apparent adverse effects.[65] Most clinicians recommend administering a bronchodilator before the glucocorticoid formulation in the initial treatment of RAO or IAD.[26] Once the disease is in remission, chronic therapy can be continued with glucocorticoids in conjunction with environmental management.

4.4.3 Chloride Channel Blockers

Cromolyn sodium and *nedocromil sodium* are chloride channel blockers that modulate mast cell mediator release and eosinophil recruitment. Cromolyn was previously available as an equine formulation for nebulization and was efficacious as prophylactic therapy in horses with RAO.[68–71] Cromolyn and nedocromil have strong human safety profiles and similar efficacy.[72] Currently, they are available in MDIs. In human beings the clinical response to either drug is less predictable than the response to corticosteroids.[73] Because cromolyn and nedocromil must be administered prophylactically, they have limited use for treating chronic RAO and IAD.

5 CHAPTER 5 APPLIED NUTRITION

Debra K. Rooney

Basic knowledge of the proper method for feeding horses is important to veterinarians so that they may assist their clients in detemining feed choices that are wholesome, economical, and tailored to the workload or intended use of the horses. In addition, many veterinarians operate a boarding or breeding facility and need to provide balanced rations to the horses in their care. To help the client best, the veterinarians should know the number, type, and use of the horses. Client preference regarding feeds is also important because the choice may be determined or governed at least partially by the amount of staff available and the ability of the staff to comply with detailed instructions.

The basic considerations for the amount and type of feed are determined by the age, size, and use or workload of the horses.[1,2] Broodmares have needs different from growing horses, which are different from horses in heavy work. The nutritional management of orphaned foals and sick neonates or adult horses with serious infectious diseases or neoplasia requires special dietary consideration.

5.1 Feeds

5.1.1 FORAGES

The most common forms of forage fed to horses are pasture and hay. Silage, haylage, and "green chop" also have been used to a much lesser extent. The choice of forage type depends on several factors: land availability, fertility of the soil, storage capability, and climate. Regardless of the form, the quality of the forage fed is dictated by the species, soil fertility, temperature, degree of rainfall, method of harvesting, and most important, the stage of maturity at harvest. The best-quality forages are cut before seed heads (boot stage in grasses) and blooms (bud stage for legumes) appear. This results in a higher proportion of leaves, a decrease in the poorly digestible cell wall content, and consequently a more nutritious product. Hay cubes are fed less often but can be useful when limited storage space is available.

5.1.1.1 Grasses

The grass species generally are divided into two groups: the cool-season and the warm-season grasses. The cool-season grasses include Kentucky bluegrass, smooth bromegrass, orchard grass, tall fescue, timothy, and oats. These grasses are grown predominantly in the northern half of the United States. These species are of greatest value in the spring and fall, providing a forage stand that is lush and high in nutritive value and palatability.

5.1.1.1.1 Kentucky Bluegrass

Long favored by horsepersons everywhere as the ideal pasture grass, bluegrass is highly palatable and winter hardy and is a ready volunteer, producing high yields in the cooler months. Bluegrass seems to handle close grazing well; however, it does not do well in the summer months or under heavy traffic. Kentucky bluegrass is used exclusively in pastures.

5.1.1.1.2 Smooth Bromegrass

Like bluegrass, bromegrass forms a dense sod and is winter hardy. Unlike bluegrass, bromegrass is heat and drought tolerant. Its good palatability, even when mature, makes bromegrass a good choice for pasture or hay when seeded with alfalfa. Bromegrass does not tolerate overgrazing or frequent harvesting and is slow to regrow.

5.1.1.1.3 Orchard Grass

Another common grass species in the temperate zones, orchard grass produces early growth; is more heat, 235
shade, and drought tolerant than most grasses; and recovers rapidly after harvest or grazing with good- 236
quality growth. Its early maturity makes orchard grass compatible in seedings with alfalfa. Orchard grass is less winter hardy than other species.

5.1.1.1.4 Tall Fescue

Of the grasses, tall fescue is the most traffic and drought tolerant. Fescue adapts to a wide range of soil and climate conditions and is persistent. Palatability is generally not high but improves in the spring and following the first frost. The biggest drawbacks to using tall fescue in pastures are the high concentration of alkaloids and the more recent problems associated with endophyte infestations or fescue toxicosis that have serious consequences in broodmare bands.[3] The problem often affects broodmares in late pregnancy and young growing horses. The endophytic fungus *Acremonium coenophialum* affects growing pasture and sometimes hay made from these pastures. (For additional information, see Chapter 20.)

5.1.1.1.5 Timothy

The most well known of the grasses and the most popular of the grass hays, timothy is winter hardy, easy to establish, and widely adapted. Timothy is generally a clean, dust-free hay and is consumed readily by horses. Timothy is not a good pasture grass because of its low tolerance for heavy grazing or cutting and the production of an open, clumpy sod. Like most grasses, timothy is not as heat or drought tolerant as legumes.

5.1.1.1.6 Oat Hay

A popular forage in the western United States and Canada, oat hay is best if harvested when the grain is at the late milk or dough stage. When cut at the proper time, the protein content can be as high as 13%. A valid concern is the potential for nitrate poisoning if oat hay is harvested at a young stage, and testing for nitrate concentration is recommended if oat hay is going to be used as the predominant forage source. Concentrations of nitrates between 0.4% and 0.6% are considered safe for horses.[1] For further discussion, see Chapter 20.

The warm-season grasses Bermuda grass, Bahia grass, and pangola grass do well in sandy soils, are more drought tolerant, but are generally lower in digestibility than the cool-season grasses and often produce lower yields. These forages are found primarily in the southern coastal and southeastern regions of the United States. Most are used as pasture grasses. The exception is Bermuda grass, which also can serve as an easily harvested, high-yielding species for hay production.

5.1.1.2

Legumes

Alfalfa and clover are the predominant legume species. In some areas of the country, stands of bird's-foot trefoil and lespedeza (also called *Sericea*) still are grown. The deep-rooted characteristic of legumes is what contributes to their drought tolerance. Their high protein and calcium content is useful in improving the nutritional value of grass pastures. A disadvantage of legumes is their intolerance to heavy traffic, overgrazing, and poor drainage.

5.1.1.2.1

Alfalfa

Alfalfa has become the predominant legume grown in the United States. Alfalfa is leafy and fine stemmed, produces high yields, is resistant to many pests and diseases, and is high in digestibility and palatability. Despite these advantages, many wives' tales and myths exist that make its use controversial. No data support the long-held contention that the protein content makes it too “rich” for horses and, likewise, that it causes kidney damage. The high protein and mineral content of alfalfa stimulates an increase in water intake and a concomitant increase in urine volume and nitrogen and calcium excretion. Alfalfa also has been called a “hot” feed, but research has shown that no difference exists in sweat production or body temperature in horses fed alfalfa or timothy hay.[1]

The major concerns with alfalfa are the wide calcium-to-phosphorus ratios that can occur, the potential for overfeeding, and the problems with blister beetle infestation. Most alfalfa hays have calcium-to-phosphorus ratios between 3:1 and 5:1, but ratios as high as 15:1 have been observed.[1] Mature horses can tolerate ratios of the total diet as high as 6:1, but some mature horses have developed a propensity for dirt-eating or rock-chewing suggestive of pica at calcium-to-phosphorus ratios of 3:1. Ratios higher than 3:1 are not advised for young, growing horses.[2] When the use of alfalfa results in undesirable ratios, adding phosphorus to the diet or reducing the amount of alfalfa by replacing it with a grass hay should narrow the ratio.

The digestible energy content of alfalfa is generally higher than other forages, making it much easier to overfeed. Fourteen pounds of alfalfa hay is equal in energy content to 18 lb of timothy hay. Horses fed high-quality alfalfa (>55% total digestible nutrients) at 2% of their body weight can become fat quickly, consuming in some cases 50% more calories than required for maintenance. One can feed less alfalfa and still meet the needs of the animal. Supplying some grass hay should help to appease boredom if additional forage seems indicated.

Cantharidin toxicosis from the ingestion of blister beetles was first reported in horses in 1978.[4] (See Chapter 20 for a thorough discussion of cantharidin poisoning.)

5.1.1.2.2

Red and White Clover

Red clover still is preferred by some horsepersons but has declined in popularity. When harvested properly, red clover can be as high in nutritive value as alfalfa. Because cutting clover at an earlier stage of maturity reduces yield, most is cut well beyond the bloom stage. This results in a coarse, thick-stemmed forage that becomes moldy, dark, and dusty when baled.

Red clover also can be infected by *Rhizoctonia leguminicola,* a fungus that produces an alkaloid called slaframine, resulting in the condition known as “slobbers.” Excessive salivation is the most consistent 236

clinical sign, though abortion in a mare also has been reported.[5] Once the affected forage is removed, salivation ceases. White and ladino clovers, known for their high proportion of leaves, are used primarily as pasture forages. Neither clover is particularly winter hardy or shade tolerant.

5.1.1.2.3 Bird's-Foot Trefoil

Bird's-foot trefoil still is grown in parts of the temperate zone but has lost favor with many producers because it is difficult to establish, is weak-stemmed, and is slow to recover from grazing. The forage was named for the crow's foot–like seed pod that develops in the fall. Like the other legumes, bird's-foot trefoil can be high in feeding value when harvested properly.

5.1.1.2.4 Alsike and Sweet Clover

Alsike and sweet clover are not commonly fed to horses and for good reason. Mild to severe photosensitization reactions and hepatitis have been reported in horses consuming Alsike clover.[6] The stemmy consistency of sweet clover makes it difficult to cure for hay, increasing its susceptibility to mold. Common molds such as *Penicillium* species can convert coumarin, a nontoxic substance in sweet clover, to dicumarol. Dicumarol interferes with the activation of vitamin K, making it a potent anticoagulant. One should avoid using these two forages if at all possible.

5.1.2 PASTURE

When well cared for, pasture is the most inexpensive and nutritious form of forage. A combination of grasses and legumes typically are used, taking advantage of the drought-resistant, high-calcium content of the legumes and the traffic resistance and early growth characteristics of grasses. The perfect or ideal pasture is obtained by cultivating those species that have adapted to that area and are compatible with the soil and drainage conditions. The best sources for this information are extension agencies or agronomy departments at universities.

Well-managed pastures can provide ample forage stocked at a rate of one horse per acre. Where space is limited or management is difficult, nearly 8 to 10 acres per horse may be needed. To maintain good, safe pastures, agronomists suggest (1) routine soil testing; (2) clipping to reduce weeds and stimulate new growth; (3) removal of toxic weeds; (4) rotation, if possible; (5) maintaining optimal stocking rates; (6) the proper mixture of grass and legume species; and (7) the spreading or removal of manure to prevent burning and increase the usable acreage.

5.1.3 HAY

Any hay can be the best hay for horses as long as it is cut at the proper stage of maturity. As forage matures, its nutrient content, especially the protein content and protein digestibility, decreases. The more youthful the plant, the higher the leaf content and the higher the nutritive value, for 80% of the nutrients are found in the leaves. Quality hay is free of mold, dust, and weeds; has few if any seed heads; is soft to the touch; and has a pleasant aroma. Probably the best determinant of quality is intake; horses devour high-quality hays with relish.

Hay can be chopped, pelleted, cubed, or fed long stem from the square or round bale. Alfalfa cubes are usually of good quality because of the amount of leaf that is needed for cubing. Waste and storage space are less with cubes. One disadvantage is the boredom that may occur because it takes the horse less time to eat the cubes than the equivalent weight in long-stem hay. Choking is a frequently cited concern but would seem to be reserved for

the greedy eater. Before purchasing cubes, one should ask for the name and address of the manufacturer and should inspect a sample for the presence of foreign materials such as twine, newspaper, or insects. Alfalfa pellets are also available but have their greatest use in mashes. The pellets tend to be more dusty and crumble more easily, increasing wastage. Because of their small size, horses consume pellets much more quickly, which may result in an increase in delinquent activities such as wood chewing, cribbing, or consumption of bedding to appease the desire to chew if alfalfa pellets are the sole source of forage. Chopped hay has been shown to decrease the rate of consumption when mixed with grain[1] and has been used successfully in group-feeding situations to prevent overeating.

5.1.4 GRASS CLIPPINGS

One can feed fresh lawn or pasture trimmings to horses, with several provisos. Anyone who has prepared compost is familiar with the heat that is produced in the center of the pile as a result of the favorable microbial environment; that is, dark, moist, high in carbohydrates, and ultimately anaerobic.

Pockets of mold can develop within the mass that may have unfavorable consequences for the horse. One can prevent mold growth by spreading out what the horse will consume in 30 to 60 minutes and discarding any remaining. Moreover, grass from well-tended yards may contain high concentrations of nitrates from frequent fertilizer applications and should be fed judiciously.

5.1.5 GRAINS

Grains provide a more concentrated source of energy. Compared with some forages, such as grass hays, grains can provide 50% to 100% more digestible energy per pound and in a smaller volume. The feed grains vary in size, weight per unit volume, and nutrient content. For this reason, one should feed grains by weight and not volume (e.g., coffee can or scoop). Processes such as rolling, crimping, cracking, steam flaking, and popping can
improve digestibility, particularly for foals and horses that have difficulty chewing or have poor teeth. One 237
usually can obtain the nutrient value of grains or grain mixtures from the feed tag or feed tables or by requesting 238
a nutrient analysis from the manufacturer or feed dealer. If a guaranteed analysis is not available, the veterinarian should encourage the client to have the feed analyzed.

5.1.5.1 Oats

Oats have long been the favorite and preferred grain of horsepersons. Oats contain approximately 10% fiber, the highest of the feed grains. Oats are therefore bulkier than the other grains, helping to reduce the risk of overconsumption. Protein content varies from as low as 8% for "light" oats to as high as 12% for the heavy Swedish oats. When one purchases oats, they should be large, plump, and clean. The heavier the oat weight per bushel, the higher the energy content. Top-quality oats today can weigh as much as 42 lb per bushel compared with the standard bushel weight of 32 lb. "Clipped" oats have had the ends of the hulls removed. Crimping or rolling is recommended only for foals and horses that cannot chew their food well.

The claim that oats make a horse high or excitable ("feeling their oats") is old and is unfounded. No substances in oats are known to produce this effect other than extra calories making the horse feel more energetic.

5.1.5.2

Corn

The use of corn is increasing as the cost of oats becomes more prohibitive. Corn is energy dense, containing approximately 1.5 Mcal/lb. The reputation of corn as a hot feed is unsubstantiated, other than through wives' tales, producing no more heat from digestion than any other grain and far less than hay. Corn is the heaviest grain per unit volume and therefore has the highest risk of being overfed if not managed properly. Corn is low in protein (8% to 9%) and low in fiber (2% to 3%) compared with the other feed grains but is the only grain used commonly in horse feeds that contains vitamin A. Corn also is graded by weight, the top grade weighing a minimum of 56 lb per bushel. Corn most often is fed whole or cracked, but steam-rolled, steam-flaked, and steam-popped corns are gaining in popularity for use in textured ("sweet") feeds. Ground corn is not recommended because it is dusty. One also may feed corn from the cob, but one should watch horses carefully because cobs have become lodged in the mouths and throats of horses.

Of the grains, corn seems to have a greater potential for supporting mold growth. More recent concerns have involved outbreaks of aflatoxicosis and leukoencephalomalacia in horses caused by toxins produced by *Aspergillus flavus* and *Fusarium moniliforme,* respectively.[7] In response, feed companies voluntarily began screening corn shipments for the presence of aflatoxins, reducing the threat of commercial feed contamination. To stop the use of corn in feeds based on these isolated incidents is not reasonable. As with all grains, one should never use feed with an off odor or that appears moldy.

5.1.5.3

Barley

Barley is used more on the West Coast and in the far north. This grain is an excellent choice for horses. The protein and digestible energy content of barley falls between corn and oats. Because of the small size and tenacious seed coat, barley should be crimped or rolled to improve digestibility.

5.1.5.4

Sorghum or Milo

This southern-grown feed grain is not used widely as an energy source for horses. Like corn, sorghum is high in energy and low in fiber, and therefore the same cautions regarding overfeeding apply. Sorghum also should be rolled, crimped, or steam flaked for improved digestibility.

5.1.5.5

Rye

Rye has been fed to horses but is not used commonly today. Rye is similar in nutrient content to barley. The low palatability, concern of ergot poisoning, and the bounty of other more suitable grains have reduced its use in feeds.

5.1.5.6

Wheat

Wheat is occasionally available for use as feed, though it is expensive. Wheat is similar in nutrient content to barley. Because of its small size, processing by steam crimping or rolling is highly recommended. Wheat has a reputation of forming doughy masses in the stomach and is generally limited to one third of the grain mix.

5.1.6 PROTEIN SUPPLEMENTS

The level of protein required in the diet of horses is influenced by physiologic status (e.g., growth, maintenance, and gestation), protein source, and feed intake. The plant protein sources are used most often in horse feeds and include soybean, cottonseed, linseed, peanut, and sunflower meals. Soybean meal is by far the leading protein supplement, contains 44% protein, and is the highest in lysine (2.8% to 3.0%), an essential amino acid. Soybeans must be toasted to inactivate trypsin inhibitors but not overheated so as to reduce amino acid availability. Interestingly, soybean meal has been found to contain goitrogens, anticoagulant factors, and phytoestrogens. These do not appear to result in problems in horses.

Other seed meals are used to a much lesser degree and tend to be regional. Cottonseed and peanut meal is used mostly in the South. Though cottonseed can be a good protein source when supplemented with lysine,[8] the 238
presence of gossypol, an antioxidant and cardiotoxin,[9] reduces its acceptability by horsepersons. Peanut meal is 239
also limited in lysine, somewhat expensive, and risky to feed because it can be a source of aflatoxins.[10] Sunflower meal is low in lysine but higher in methionine.

Linseed meal is known more commonly for its ability to impart a sheen to the hair coat than as a protein supplement. Immature seed can contain the cyanogenic glycoside linamarin and its enzyme linase, both of which are destroyed by heat-processing.[11] Linseed meal is also low in lysine. Low production and expense have reduced its use in animal feeds.

Urea also has been used as a nonprotein nitrogen source for adult horses but has no advantage over more common sources.[12,13] Horses are not as efficient in using urea as are cattle and are much more tolerant to excessive levels. Urea toxicity is less likely in horses because urea is absorbed by the gastrointestinal tract and excreted in the urine before reaching the hindgut, where the microbial population hydrolyzes urea to ammonia and carbon dioxide via urease. Urea toxicosis has been produced in ponies experimentally by oral dosing of 5 g urea per kilogram of body mass.[14] The clinical signs of urea toxicity are confined to the central nervous system, with muscle tremor, incoordination, and weakness. Death is the result of ammonia intoxication.

5.1.7 BY-PRODUCT FEEDS

A variety of feedstuffs are "waste" products of the feed and food industry. Some can add extra fiber, and others serve as energy sources. These by-products include cottonseed hulls, peanut hulls, soybean hulls, wheat bran, wheat middlings, dried brewer's and distiller's grains, citrus pulp, and dried whey, to name but a few. Other by-products may be available by region. One by-product that is becoming increasingly popular is beet pulp. A by-product of the sugar industry, beet pulp is added to textured feeds as a fiber source. The primary markets for these feeds have been owners of racing horses and horses with hay allergies or respiratory diseases, most notably heaves. Beet pulp is high in digestible energy and provides some dietary calcium. Though feeds containing beet pulp are bulky, horses do develop vices and bad habits from grazing boredom if some long-stem hay is also not made available.

5.1.8 VITAMIN AND MINERAL SUPPLEMENTS

The National Research Council (NRC) recommendations for vitamins in horses are restricted to vitamins A, D, and E; thiamine; and riboflavin. Table 5-1 lists the sources commonly used to supplement vitamins in most feeds. As ingredients, vitamins vary in price, regional availability, solubility, potency, and stability.

For minerals the sulfate forms of supplements are generally higher in availability than the carbonate or oxide form. Newest additions to the trace mineral supplements are the chelated minerals. These are trace elements bound to amino acids, peptides, or polysaccharides, with the goal of decreasing the opportunity for mineral antagonisms and increasing absorption. Whether they are in fact superior to inorganic forms in availability or efficacy remains to be determined in the horse. Chelated minerals are more expensive than the inorganic forms but may prove advantageous in improving the palatability of feeds containing high concentrations of minerals. Table 5-2 provides a list of mineral sources.

TABLE 5-1 Commonly Used Vitamin Sources in Horse Feeds

VITAMIN	SOURCE
Biotin	*d*-Biotin
Choline	Choline chloride
Cyanocobalamin (B_{12})	Cyanocobalamin
Folacin (folic acid)	Folacin
Niacin	Nicotinic acid
	Nicotinamide
Pantothenic acid	Calcium pantothenate
Pyridoxine (B_6)	Pyridoxine hydrochloride
Riboflavin (B_2)	Riboflavin
Thiamine (B_1)	Thiamine hydrochloride
	Thiamine mononitrate
Vitamin A	Vitamin A acetate
	Vitamin A palmitate
	Vitamin A propionate
	β-Carotene (precursor)
Vitamin C	Ascorbic acid
Vitamin D	Activated animal sterol (D_3)
	Cholecalciferol
	Ergocalciferol (D_2)
Vitamin E	α-Tocopherol acetate
	α-Tocopheryl acetate
Vitamin K	Menadione sodium bisulfite

5.2 Nutrition of the Mature Horse

One can meet the nutrient requirements of the mature horse under most circumstances by feeding a good-quality hay, water, and a salt block supplemented with trace minerals. The rule of thumb of providing 2% of body weight per day in dry feed is still a good rule to follow. Contrary to the practices of most owners, grain is needed only when hay alone cannot meet energy needs. Supplementation with grain may be necessary when the exercise plane increases or forage quality decreases. Overnutrition from feeding excess grain and empirical supplementation of vitamins and minerals are of more concern today than are dietary deficiencies. Table 5-3 summarizes the nutrient requirements of the mature horse.

239

TABLE 5-2 Commonly Used Mineral Sources in Horse Feeds

MINERAL	SOURCE	MINERAL CONTENT
Calcium, phosphorus	Limestone	38% Ca
	Dicalcium phosphate (dynafos)	20% Ca, 18% P
	Mono-and dicalcium phosphate (biofos)	18% Ca, 21% P
	Tricalcium phosphate	38% Ca, 18% P
	Monosodium phosphate (monofos)	22% P, 17% Na
	Sodium tripolyphosphate	25% P, 31% Na
Magnesium	Magnesium sulfate	20% Mg
	Magnesium oxide	28% Mg
Potassium	Potassium chloride	52% K
	Potassium sulfate	45% K
Sodium	Sodium chloride	39% Na, 61% Cl
Copper	Copper sulfate	25% Cu
	Copper oxide	80% Cu
	Copper carbonate	57% Cu
	Copper proteinate	10%-13% Cu
Manganese	Manganese sulfate	23% Mn
	Manganous oxide	77% Mn
	Manganous sulfate	32% Mn
	Manganese proteinate	15% Mn
Cobalt	Cobalt carbonate	49% Co
	Cobalt sulfate	38% Co
	Cobalt proteinate	9%-11% Co
Iron	Ferric carbonate	48% Fe
	Ferric chloride	21% Fe
	Ferric ammonium citrate	17% Fe
	Ferrous fumarate	33% Fe
	Ferric oxide	70% Fe
	Ferrous sulfate	20%-30% Fe
	Iron dextran	2%-5% Fe

Zinc	Zinc sulfate	22%-36% Zn
	Zinc oxide	80% Zn
	Zinc proteinate	15%-22% Zn
	Zinc methionine	Not available
Iodine	Ethylenediaminedi-hydroiodide	77% I
	Potassium iodide	76% I
	Calcium iodide	65% I
Selenium	Sodium selenite	45% Se

5.2.1 ENERGY

The energy needs of the mature horse can vary. The digestible energy (DE) requirement for field maintenance allows for what is necessary to maintain body mass (BM) and daily, nonworking activity (searching for food, socialization). For horses under 600 kg, one can calculate the DE from the following equation[15]:

$$0.021(BM_{kg}) + 0.975 = \text{Mcal DE per day}$$

For horses greater than 600 kg, one can use the following equation:

$$0.0383(BM_{kg}) - 0.000015(BM_{kg})^2 + 1.82 = \text{Mcal DE per day}$$

The latter equation allows for the decrease in voluntary activity observed in the larger breeds.[2] Both of these estimates apply to horses maintained out of doors in pastures, paddocks, or dry lots. For stall-bound horses, the amount of energy expended for activity and thermoregulation has been reduced. The resting energy expenditure of horses in stalls calculated from the following equation is probably closer to the energy needs of most pleasure and halter horses.[15]

$$0.021(BM_{kg}) + 0.975 = \text{Mcal DE per day}$$

For owners periodically to obtain the body weight and to assess the condition of their horses to prevent undesirable weight gain is important. Cloth weight tapes provide a quick and reasonably accurate estimate. One also can calculate the body weight using the equations based on chest girth[16] (Box 5-1). For accuracy, one should take this measurement at the base of the withers and pull the tape snugly without embedding the tape in the skin. One also should evaluate body condition scores. Table 5-4 provides descriptions of body conditions rated on a scale of 1 to 9.[17] Horses, regardless of age, are kept best at a score of 4 to 5, so that one can barely see but easily feel the ribs.

The requirements for work expenditure have been calculated using the weight of the horse, rider, and tack and the workload.[18,19] For practical purposes, increases over maintenance of 25% for pleasure and equitation; 50% for roping, cutting, and jumping; and 100% for distance training and polo should be a reasonable guide. One should base adjustments in feed intake on body condition.

5.2.2 PROTEIN

The protein requirement of the mature horse is roughly 1.3 g of crude protein per kilogram of body mass or 40 g/Mcal of DE.[2] However, because protein is not used as an important fuel source in horses, a level of 12% of dry matter is adequate for most horses. Quality of protein is less important for mature horses than for the growing horse but should not be overlooked. Despite a widespread belief, excess protein does not cause kidney damage in healthy horses. Feeding more protein than is necessary is expensive for the owner and only harmful to the pocketbook.

5.2.3 MINERALS

For the mature horse the major mineral needs are met with the consumption of good-quality feed to meet energy and protein needs. Trace mineral salt blocks are recommended strongly to provide the sodium, zinc, and iodine
not found in most feeds. In areas where selenium is deficient, a salt block with added selenium is required. 240
Unlike salt used for human consumption, most white salt blocks do not contain iodine and should be replaced 241
with trace mineral blocks containing iodine. The label found on the block or brick provides the mineral content.

TABLE 5-3 Daily Nutrient Requirements of the Mature Horse*

NUTRIENT	STALL REST	MAINTENANCE	PROVIDED BY 13 lbALFALFA† 2 ozTM SALT‡	PROVIDED BY 16 lb GRASS† 1 lb PVM§

5.2.4 VITAMINS

A horse consuming good-quality hay or pasture receives all the necessary vitamins directly from the feed, body stores (fat-soluble vitamins), or by microbial synthesis in the hindgut. Naturally occurring B vitamin deficiencies have been reported only in cases in which dietary or chemical antagonists were present.[20,21] When one feeds poor-quality hay, the addition of a commercial feed to supplement energy intake provides the needed vitamins.

5.2.5 GENERAL GUIDELINES

Providing 1.5% to 2.0% of the body weight in feed per day meets the needs of most horses. For grass hays, a
1000-lb horse kept on dry lot or minimal pasture needs approximately 18 lb/day. If one feeds alfalfa hay, only 14 241
lb provides the same amount of energy for field maintenance because of the higher energy content. If one feeds 242
grain, the ratio by weight of hay to grain should not exceed 50:50. Plenty of clean, fresh, cool water should be available at all times. Water intake appears to be related directly to dry matter intake.[22] Most horses consume a minimum of 1 L/Mcal of DE or 2 to 3 L/kg dry feed.

5.2.5.1 BOX 5-1 EQUATIONS FOR ALCULATING BODY WEIGHT FROM CHEST GIRTH (CG) MEASUREMENTS*

Chest girth >66 inches:	
Males	0.14475 (CG_{in}) = Body weight, lb
Females	0.14341 (CG_{in}) = Body weight, lb
Chest girth <66 inches (including foals):	
Colts	0.1387 (CG_{in}) + 0.400 = Body weight, lb
Fillies	0.1382 (CG_{in}) ++ 0.344 = Body weight, lb

Modified from Willoughby DP: *Growth and nutrition in the horse,* Cranbury, NJ, 1975, AS Barnes.

* Use the adult formulae for mature ponies.

TABLE 5-4 Description of Body Condition Scores

SCORE	DESCRIPTION
1 Poor	Animal extremely emaciated; spinous processes, ribs, tailhead, tuber coxae, and tuber ishcii project prominently; bone structure of withers, shoulders, and neck easily noticeable; no fatty tissues can be felt.
2 Very thin	Animal emaciated; slight fat covers over base of spinous processes; transverse processes of lumbar vertebrae feel rounded; spinous processes, ribs, tailhead, tuber coxae, and tuber ischii prominent; withers, shoulders, and neck structures faintly discernible.
3 Thin	Fat buildup about halfway on spinous processes; transverse processes cannot be felt; slight fat covers over ribs; spinous processes and ribs easily discernible; tailhead prominent, but individual vertebrae cannot be identified visually; tubera coxae appear rounded but easily discernible; tuber ischii not distinguishable; withers, shoulders, and neck accentuated.
4 Moderately thin	Slight ridge along back; faint outline of ribs discernible; tailhead prominence depends on conformation, and fat can be felt around it; tuber coxae not discernible; withers, shoulders, and neck not obviously thin.
5 Moderate	Back is flat (no crease or ridge); ribs not visually distinguishable but easily felt; fat around tailhead beginning to feel spongy; withers appear rounded over spinous processes; shoulders and neck blend smoothly into body.
6 Moderately fleshy	May have slight crease down back; fat over ribs is spongy; fat around tailhead feels soft; fat beginning to be deposited along the sides of the withers, behind the shoulder, and along the side of the neck.
7 Fleshy	May have crease down back; individual ribs can be felt, but filling between ribs with fat is noticeable; fat around tailhead is soft; fat deposited along withers, behind shoulders, and along the neck.
8 Fat	Crease down back; difficult to feel ribs; fat around tailhead very soft; area along withers filled with fat; area behind shoulder filled with fat; noticeable thickening of neck; fat deposited along inner thighs.
9 Extremely fat	Obvious crease down back; patchy fat appearing over ribs; bulging fat around tailhead, along withers, behind shoulders, and along neck; fat along inner thighs may rub together; flank filled with fat.

Modified from Nutritional Research Council: *Nutrient requirements of horses,* Washington, DC, 1989, National Academy Press.

5.3 Nutrition of the Stallion and Broodmare

5.3.1 STALLION

Nutritional management of the stallion differs little from that described for the mature horse. During breeding season, an increase in energy intake generally is needed to compensate for the increase in activity and stress. Adjustments in feed intake should be gradual. One should increase feed to provide enough energy to maintain the stallion at the desired weight and condition. The horse may need an average increase of 25% more than

maintenance. The usual energy requirement for stallions in the nonbreeding season is about 15 kcal/lb body weight and about 19 kcal/lb body weight during the breeding season.

Obesity is not an uncommon problem in stallions, particularly in the off season. Obesity occurs when the quantity of feed is not reduced when activity level decreases, resulting in overfeeding. The consensus of stallion managers is that stallions kept in good body condition through dietary control, exercise, or both are more sound, more responsive, and fertile and remain healthier than stallions that are permitted to become obese. To help maintain optimal body weight during the breeding season, one should turn out stallions or exercise them in hand for a few hours each day.

Contrary to popular belief, no evidence indicates that extra minerals or vitamins are required for breeding stallions other than those for maintenance. Stallions with access to well-managed pasture or that are receiving good-quality hay and trace mineral salt derive little benefit from additional supplementation. The testicular degeneration reported in rats fed vitamin E–deficient diets has not been observed in horses, and no evidence indicates that vitamin E, A, or C supplementation improves libido or prevents sterility in the stallion.[23,24] However, no evidence indicates that supplementation of these vitamins is harmful.

5.3.2 OPEN MARE

One should feed mares with a condition score of 5 or 6 according to the guidelines for the mature horse. One should place mares that have retired recently from athletic competition or may be in poor condition in a weight- 242
gaining plane before breeding to increase the likelihood of conception and improve reproductive efficiency. 243
Recent research indicated that "flushing," or increasing the energy intake approximately 10% to 15% more than maintenance, increased the chance of conception and reduced the number of covers for mares with a body condition of 4 or lower.[17] No advantage accrues to overfeeding the fat mare. Obesity has been cited as a contributing cause to angular limb deformities in foals and reduced conception rates.[25,26] As in stallions, no evidence indicates that supplementation of other nutrients beyond requirements enhances reproductive performance.

5.3.3 PREGNANT MARE

One should feed the nonlactating mare in early and midgestation to meet maintenance requirements (Table 5-5). The early growth of the fetus is minimal and does little to increase nutrient demand. Often mares are "fed for two" early in pregnancy, which can result in higher feed costs and, more commonly, undesirable weight gain. Recent research suggests that weight gain occurs during midgestation for use as a source of energy later in gestation,[26,27] but no advantage seems to accrue from gains greater than 12% to 15%. One should include additional calories and other nutrients to support lactation and athletic activity in the dietary plan.

The greatest increase in fetal growth and nutrient demand occurs during the last 3 to 4 months of gestation[28–30] (Table 5-6), necessitating increases in most nutrients to support growth and development. Supplying the extra nutrients is confounded, however, by the reduction in digestive capacity as a result of the increasing size of the fetus. The solution is to increase the nutrient concentration and, in some cases, the quality of the feed.

The increases in energy intake for the mare in the last trimester were based on the energy content of equine fetal growth in the last 3 months of gestation. Estimates of the DE requirements for broodmares are 1.11, 1.13, and 1.2 times the maintenance requirement for the ninth, tenth, and eleventh month, respectively,[2] but may be higher for mares in poor condition.[31] For the 1100-lb mare at field maintenance, this increase would equal an additional

1.64, 2.10, and 3.28 Mcal/day during months 9, 10, and 11, respectively. One can meet these increases easily by an additional 11 lb of fresh pasture, 2 to 3 lb of hay per day, or 2 lb of grain, demonstrating that large quantities of feed are not required. In cases in which grass hay is the primary forage, a proportional increase in concentrate to 20% to 30% and a decrease in roughage to 70% to 80% usually provides the energy needed. One should monitor mares as previously described to prevent undesired increases in condition score. Decreases in energy intake to encourage weight loss (>10%) in obese mares is not recommended because of the potential risk of hyperlipemia.[32]

TABLE 5-5 Nutrient Requirements of the Gestating and Lactating Mare[*]

* Mares weighing 450 to 600 kg. Energy need may vary according to age, desired body condition, and milk production.

† No requirement established.

A 10% increase in protein intake has been recommended for protein accretion of the fetus.[2] In nearly all cases, the additional feed provided to meet energy needs supplies the extra protein. The effects of higher intakes of protein on fetal health have not been evaluated, but the fact that many mares fed alfalfa consume nearly twice their requirement for protein and produce healthy, vigorous foals suggests that there should be little concern.

Recent studies of fetal growth, body composition, and postnatal development have provided some estimates of mineral needs during the last 3 to 4 months of pregnancy.[33] Data suggest that to provide for fetal mineral deposition, the calcium and phosphorus intake must increase by nearly 80% more than maintenance; magnesium and potassium must increase by 25%.[2] Because most maintenance diets provide nearly twice the NRC recommendation for calcium, phosphorus, and magnesium and nearly 6 times that for potassium, supplementation rarely is required. However, mares fed diets of grass hay and unfortified grain are likely to be 243
deficient in calcium and phosphorus. One should compare current intake with the recommended levels in Table 244
5-5 to determine how much extra calcium or phosphorus is needed.

TABLE 5-6 Length and Weight of Equine Fetuses by Gestational Age[*]

AGE (DAYS)	CROWN-RUMP LENGTH (cm)[*]	MASS (WEIGHT)
60	6	17 g

Researchers have had a great deal of interest in work concerning trace mineral supplementation of the late-gestation broodmare and its role in the developmental orthopedic diseases (DODs) of foals.[34,35] Though additional studies are needed, recent research has demonstrated that supplementation of copper to mares during the last 90 days of gestation and to their foals reduced the frequency of cartilage abnormalities in the foals compared with mares and foals consuming NRC-recommended concentrations of copper.[35] Another important note is that copper was not the only nutrient increased in this study. Manganese, zinc, and selenium concentrations also were increased between diets to prevent antagonisms, but nutrient ratios extrapolated from

NRC recommendations were maintained. Therefore adding copper or any mineral alone without evaluating the other minerals is not likely to be of benefit and is not recommended. Selenium and iodine are also of importance to the broodmare, but one should exercise caution to avoid oversupplementation, particularly with iodine. Foals from mares fed from 35 to 48 mg iodine per day were born with enlarged thyroid glands, characteristic of iodine toxicity.[36,37] The author currently recommends the levels of trace minerals listed in Table 5-5 for broodmare diets on farms where nutrition is believed to be a contributing factor to the occurrence of the DODs. In most situations, the recommendations given for early gestation may be sufficient.

Of the vitamins, A, E, and folate are of greatest concern. Studies have demonstrated that serum concentrations of these vitamins are higher in pastured horses and decrease when diets of hay and grain are fed,[38,39] suggesting the potential for deficiencies. However, the decreases in serum concentrations were not associated with clinical evidence of vitamin deficiency, possibly because of the mobilization of body stores. One should evaluate the total dietary vitamin intake before recommending supplementation, and one should follow the NRC recommendations.[2] β-Carotene (1 mg = 400 IU vitamin A) has been recommended as the vitamin A supplement of choice because of its lower potential for toxicity compared with vitamin A. The authors also suggest that folate supplementation should not exceed 100 mg/day.[40]

5.3.4 LACTATING MARE

Energy requirements for the lactating mare depend largely on the volume of milk she is capable of producing. Production also is influenced by the number of previous lactations, the stage of lactation, genetic potential, nutrient supply (most notably energy and water), and foal intake.

During the first 3 months of lactation, one can expect most mares to produce between 3.0% and 3.5% of body weight in fluid milk each day, with pony mares producing slightly more at 4%.[41–43] Field experience suggests that maiden mares tend to have lower milk yields than multiparous mares. One can expect peak lactation to occur between 6 and 10 weeks post partum[41,44–46] but the peak of maximum production may vary and has occurred as early as 30 days.[41] As lactation continues, milk yields decline to approximately 2% of body weight.

Nutrient composition also changes during lactation (Table 5-7). Mare's milk becomes more nutrient dilute as lactation progresses. Protein, fat, vitamin, and mineral content decreases and lactose increases.[41,42,47–50] The increase in lactose content is not high enough to offset the decreases in protein and energy-dense fat, resulting in a lower calorie content.

Recent analyses of mare's milk have further characterized its unique protein distribution and amino acid profile.[51,52] Milk varies between species in its proportion of whey to casein.[53] The ratio in mare's milk is roughly 50:50 during lactation, though it is higher in whey content (85:15) during the early hours post partum.[51] This ratio is in contrast to bovine milk protein (whey- to-casein ratio of 16:82) which is primarily casein protein.[53,54] Amino acid patterns are also different among species.[52] Table 5-8 summarizes the amino acid patterns recently reported for milk from the cow, goat, sow, and mare. Unlike cow's, goat's, and sow's milk, mare's milk protein is nearly 2 times higher in arginine, a finding suggested by a study that examined growth and plasma amino acid 244
concentrations in foals receiving mare's milk or a defined formula containing bovine protein.[55] The true 245
importance of this high level of arginine remains to be determined. If the arginine is needed for optimal growth, the low level of arginine in bovine protein and consequently in most commercial milk replacers may help to

explain the less-than-optimal performance often observed in orphan foals compared with their nursing counterparts.[56,57]

The nutrients in greatest demand are water and energy, followed by protein, calcium, and phosphorus. Water is the major constituent of mare's milk, being roughly 90%. A 500-kg mare producing 15 kg milk daily would have to increase her water intake nearly twofold to replenish this loss. Additional calories also are needed. Early in lactation, mare's milk contains approximately 560 kcal/kg fluid milk.[41,42,47] Assuming that mares convert 60% of feed DE into milk gross energy, the mare must consume an extra 792 kcal of DE for every kilogram of milk produced, or an extra 11.9 Mcal in the case of the 500-kg mare, an increase of 72% more than maintenance. Protein needs have been estimated to more than double from those of maintenance from 1.3 to 2.8 g of crude protein per kilogram of body mass.[2]

* Milligrams per gram of total amino acids.

Calcium and phosphorus losses during lactation can be significant, making supplementation of these minerals essential. Mare's milk in early lactation contains 120 mg calcium and 60 mg phosphorus per kilogram of fluid milk, decreasing to 80 mg and 40 mg, respectively, in later weeks. Because only 40% to 50% of the calcium and phosphorus is available from dietary sources, supplementation of 240 mg calcium and 150 mg phosphorus per kilogram of milk seems likely. To date, no comprehensive studies have been done on the effects of dietary calcium and phosphorus intake on milk mineral content or composition.

The trace mineral and vitamin content of mare's milk is available from a limited number of studies.[48–50,58] Because no overt signs of vitamin deficiencies have been observed in nursing foals, sufficient quantities are assumed to be available. All of the trace minerals are low in milk (see Table 5-7). Increased efficiency of absorption and reliance on prenatal reserves are likely important in preventing the development of deficiencies until solid food intake begins.[48]

The point at which mare's milk and hepatic stores can no longer provide for the needs of the foal is not known. 245
Growth rate of the foal and the pre- and postpartum nutrition of the mare are two likely determining factors. The 246

fact that selenium-responsive nutritional muscular dystrophy most often occurs in nursing foals[59] and that more recent evidence demonstrates a reduction in cartilage defects following trace element supplementation at 3 months of age[35] suggests that supplementation may be needed earlier for some minerals.

Generally, body condition score is the best gauge for determining the energy needs of the lactating mare. The habit of "feeding the stall" rather than the horse often results in underfeeding the good producers and overfeeding the poor producers. Mares that lose weight during lactation should be provided with more energy, a higher quality of feed, or both, if clinical examination reveals no underlying cause. Mares that continue to gain weight during lactation are storing the energy as fat rather than channeling it toward milk production.

5.4 Nutrition of the Growing Horse

5.4.1 FOALS

The precocious nature of foals requires that they receive nutrients within hours of birth to survive. Body composition studies have shown that foals have little in energy reserves compared with the adult horse.[29,33] A readily available food source therefore is needed to fuel organ systems and red blood cells and to support thermoregulation and growth. These energy needs are met by frequent nursing,[60] an inherent ability for a high rate of water turnover,[42] and physiologic lengthening of the small intestine to increase available surface area for greater absorption.[61] Nutrition becomes of greater importance for the foals born of mares that are malnourished or that may have chronic placental insufficiency or uterine sepsis, all of which may result in small foals with low nutrient reserves.[62] Because of the increase in nutrient demand following injury or disease, supplying ample, balanced, and complete nutrition is critical for health, development, growth, and recovery.

Data collected from several studies have provided reasonable estimates for evaluating growth and growth rates of foals.[63–67] The greatest increase is in body weight. At birth, foals are approximately 11% of their adult body weight; normal birth weights for most light breeds are between 90 and 110 lb. The period of most rapid growth is the first 30 days when birth weight generally doubles. Average daily gain for the first week is 1.6 kg/day, which decreases steadily with increasing age, to 1.2 kg/day by the fourth week. Tables 5-9 and 5-10 present the reported body weights, rates of weight gain, and relationship to adult weight for growing foals.

Foals are roughly 60% of their adult height at birth.[1] Accurate measurement of wither heights at birth is complicated by the tendon laxity frequently encountered in neonates, but most foals are between 38 and 42 inches high. As with weight, growth rate in height is greatest the first week and then steadily declines. Tables 5-9 and 5-10 show wither heights, rates of height gain, and comparisons with adult measurements.

TABLE 5-9 Reported Growth Rates for Healthy Foals

AGE	WEIGHT (kg/DAY)	HEIGHT (cm/DAY)
First week	1.6	0.4
Second week	1.5	0.35
Birth to 4 weeks	1.4	0.32–0.33
4–8 weeks	1.3	0.25–0.26
8–12 weeks	1.1	0.20–0.25

Data from references 63 to 65 and D.A. Knight, Columbus, Ohio.

Data collected from lactation and growth studies have provided some estimate of the energy, protein, calcium, and phosphorus needed to support early growth in healthy foals. Nursing foals consume approximately 150 kcal gross energy per kilogram of body mass during the first week.[42,43,46] This consumption equals 13 to 14 qt of mare's milk per day for light horse foals or 15 to 17 qt/day for large Warmblood or Draft foals. Similarly, protein needs are high: 6 to 7 g/kg body mass. As the foal ages, the growth rate slows and the energy and protein needed as a function of body weight decreases accordingly (Table 5-11). However, because the larger foal has more total mass to support, the volume of milk needed to meet the requirements increases.

TABLE 5-10 Estimated Body Weight and Wither Height Ranges for Growing Horses of Light Breeds

AGE	MASS (kg)	PERCENT OF MATURE MASS*	HEIGHT (cm)	PERCENT OF MATURE HEIGHT*
Birth	50 ± 9	10	96 ± 5	60
14 days	73 ± 14	14	104 ± 5	65
1 month	91 ± 14	18	109 ± 5	68

246

TABLE 5-11 Estimated Calories and Volume of Mare's Milk Needed to 2 Months of Age by a 55-kg Foal at Birth

		VOLUME		
AGE	**KILOCALORIES**	**QUARTS**	**ml/hr**	**kcal/kg**
Birth to 7 days	7500	14	550	145–150
8–14 days	9800	18	700	135–145
15–28 days	11,000	20	800	100–135
1–2 months	12,500	23	900	80–100

The calcium and phosphorus concentration of mare's milk appears to be adequate in meeting the early needs of the growing foal. Because foals gradually begin to consume hay and grain during the time they are nursing, at what point these mineral needs are no longer met by milk alone is unknown. Apparently, trace element and fat-soluble vitamin stores are supplied for the short term by prenatal stores.[48–50] Trace element insufficiencies have been suggested to be responsible for some of the DODs present in growing foals and weanlings,[35,68] requiring supplementation of these nutrients before weaning.[35]

From birth the equine digestive tract undergoes anatomic and physiologic adaptions that favor the use of carbohydrates. Lactase, maltase, and sucrase activities have been measured in the small intestine of fetuses and foals.[69] Fetal disaccharidase activity is low, but lactase begins to rise within a few hours of birth. Lactase continues to be the predominant disaccharidase in the equine small intestine until 3 to 4 months of age, when the activity of maltase equals that of lactase. Maltase activity continues to rise, becoming the primary disaccharidase of the mature small intestine. As mentioned previously, the growth of various portions of the gastrointestinal tract seems to parallel these changes in enzyme activity.[61] Significant increases in the length and diameter of the small intestine occur within the first month, increasing the available villous surface area and making it possible for the foal to process increasing volumes of milk to meet its needs. During the next 5 months, growth of the small intestine continues but the greatest increases occur in the lengths of the cecum and large colon at a time when foals traditionally begin mimicking adult grazing behavior and increasing their intake of hay and grain.[70] From 6 months on, most of the growth occurs in the cecum and large intestine, allowing for the increased consumption and use of fibrous feeds.

The actual nutrient requirements of nursing foals have not been determined. From studies of foals 4 months and older, nutrient requirements have been estimated. Table 5-12 show the nutrient recommendations for foals from 4 to 6 months of age.

5.4.2 FEEDING OF ORPHAN FOALS

One can graft orphan foals onto a nurse mare or raise them by hand. One makes the best decision by evaluating several factors with the personnel who will share in the responsibility of caring for the foal.

The nurse mare has the advantage of being the most natural substitute. Nurse mares usually are purebred Draft or Draft crosses, are mild in temperament, and provide the foal with an appropriate role model. Average cost at the time of this writing was between $10 and $15 per day in the United States. In the author's experience, nurse mares are best recommended for farms where labor or technical expertise is limited and turnout is a major portion of the management. However, nurse mares have some disadvantages. Nurse mares are not readily available in many parts of the country. Not all mares are immediately compatible with the orphan, especially if the mare has had sufficient time to bond to her own foal. In some cases, several mares may be needed before a successful graft takes place. The transient nature of nurse mares increases their exposure to infectious disease and the possibility of disease transmission to the privately owned broodstock. Moreover, most leasing agreements require that the nurse mare be returned in foal, which may be difficult for farms without access to a stallion.

If one selects a nurse mare, one should ask for her foaling date and whether her foal is still at her side. A mare 4 to 6 weeks into lactation may not have the quality of milk to sustain a neonate and will have bonded to her own foal, making grafting difficult. For nurse mares to arrive at farms nearly devoid of milk because of stress or lack of mammary stimulation also is not uncommon if her foal died or was removed prematurely. Reinduction of lactation is difficult and not always successful.

Rearing by hand is accomplished by teaching the foal to drink milk substitute from a bottle or, preferably, a bucket. Teaching a foal to drink from a bucket is preferable to bottle feeding because it is less labor intensive for the owner and allows the foal to drink milk on demand. Feeding from a bucket also may help to prevent some of the behavioral problems frequently encountered with foals that have bonded to human beings. Although some of these behaviors are entertaining when the foal is small, a growing foal can cause serious injury to handlers if not reprimanded early. Foals older than 7 to 10 days of age are more difficult to train to feed from a bucket, possibly because the nursing reflex has been well established. Consideration of a nurse mare for these foals may be best.

Several milk substitutes for foals are available (Table 5-13). Selection should be based on quality, performance, acceptability, and nutritional profile. Cow's milk, goat's milk, and calf, lamb, and kid milk replacers also have 247
been used. These substitutes are different from mare's milk in several respects and are not always nutritionally 248
complete or balanced for foals (see previous discussion on feeding the lactating mare). Though goat's milk has been advocated by subjective appraisal as a suitable replacer for foals, poor weight gains and metabolic acidosis recently were reported in neonatal foals fed goat's milk to provide 135 kcal/kg/day.[71] Products containing maltodextrins, corn syrups, oligosaccharides, and glucose polymers are not recommended for foals less than 3 weeks of age because of the low level of maltase activity present in the small intestine of the foal.[69] Carbohydrates that are not digested are fermented by the microbial population of the gut and may result in excessive gas production or an osmotic diarrhea.

TABLE 5-12 Nutrient Recommendations for the Foal, Weanling, and Yearling*

NUTRIENT	FOAL†	WEANLING	YEARLING
Feed intake,% body weight	2.5–3.0	2.2–2.5	2.0–2.2

* Horses with a mature mass of 400 to 500 kg.

† Foals from 4 to 6 months of age.

‡ No requirement has been established.

Bucket training begins by isolating the foal in a deeply bedded stall for approximately 2 to 4 hours after its last meal. This acts to stimulate appetite, making the foal more willing to accept the new diet. If the foal is dehydrated, one should offer an appropriate electrolyte solution first. One should prepare the milk substitute according to package directions. A wire kitchen whisk is recommended to aid in blending and speeding the mixing process. As with any change in diet, one should offer the foal roughly half of the recommended volume for the first day or 2 rather than alter the concentration. A standard 2-gal plastic or rubber bucket is ample for most foals. For the first attempt, a full bucket is recommended to make the milk more accessible to the foal. One should encourage the foal to nurse from a finger or nipple and gently guide the foal to the bucket. Tipping the bucket slightly makes it easier for the outstretched head of the foal to contact the milk surface. Several attempts separated by rest periods usually are required before the foal nurses from the bucket on its own. Most foals learn to drink within 12 hours, but some take as long as 24 hours. Once the foal has consumed milk on its own, one should hang the bucket so that the rim is slightly higher than the point of the shoulder and assist the foal when needed. If the foal fails to nurse within 4 hours, tube feeding may be necessary because the energy reserves are minimal.

Foals generally consume 20% to 30% of their body weight in milk each day or approximately 120 to 135 ml/lb 248
of body weight for formulae with a caloric density of 500 to 650 kcal/L. As a general rule, most foals of light- 249
horse breeding need 4 or 5 gal of milk substitute each day; draft foals require 6 to 8 gals. Many foals can be fed 2 to 4 times a day. For foals requiring more observation, one may initiate a more rigorous schedule of 6 to 8 times a day with smaller volumes, with the volume increased and number of feedings decreased as the condition of the foal improves. One should mix milk replacer only as needed and not store it. One should discard milk that has not been consumed after 12 hours. One should keep all feeding equipment scrupulously clean to avoid bacterial growth and contamination.

§ As analyzed, Land O'Lakes, Inc., Fort Dodge, Iowa.

One should introduce foals to solid feeds as soon as possible. Once the foal has mastered drinking from a bucket, one should place several handfuls of high-quality hay and 0.5 lb of milk-based pellets nearby. Few foals show any interest in these feeds, but their inherent curiosity allows them to become familiar with the aroma and texture. One should increase the quantity of milk-based pellets as indicated by appetite, up to a maximum of 2 lb/day. On reaching this goal, one can add a balanced, high-quality 16% to 18% foal feed. By 2 months of age, one should discontinue liquid milk feeding; most foals are eating 2 to 2½ lb of concentrate and 2 to 3 lb of hay. By 4 to 5 months, milk-based pellets are no longer needed and can be replaced with the foal feed of choice. By 6 months, foals can consume 6 to 8 lb of foal feed and 4 to 5 lb of hay. One should feed foals to the condition in which ribs are palpable but not visible. Owners frequently confuse the presence of a potbelly with obesity. Potbellies in young horses can result from intestinal parasite burden, poor-quality feed, underfeeding, overconsumption of hay, or lack of exercise.

Ample exercise is necessary to encourage growth and proper musculoskeletal development and to ease boredom. Behaviors such as suckling the umbilical stump, prepuce, penis, stifle, or ears of other foals or animals are not uncommon and generally cease with time. Placing orphans with other weaned foals of similar age or with a placid, tolerant gelding or mare provides companionship and tutoring in equine social skills.

5.4.3 WEANLINGS

For a young horse to grow and develop properly, the diet must be in sufficient quantity and contain the appropriate balance of nutrients (see Table 5-12). Weanlings generally consume between 2.0% and 2.5% of their 249
body weight in feed per day, depending on the quality and quantity of feed available and the desired growth rate. 250
To meet their energy needs, younger weanlings should receive diets consisting of 30% to 40% grain and 60% to 70% hay. As weanlings increase in body size and digestive capacity, the proportion of grain to hay should shift in favor of more hay if the quality of the hay is high. By 12 months of age, a diet of 50% hay and 50% grain by weight is usually adequate. With the exception of exceptionally large, active individuals and the feeding of poor-quality hay, grain feeding in excess of 8 to 10 lb/day is not necessary or recommended.

Growth rates of weanlings from 6 to 12 months of age continue to decline. Weight gain decreases from 0.8 kg/day during the sixth month to 0.55 kg/day during the twelfth month. Cumulative gain in wither height drops to 0.07 cm/day. The amount of digestible energy per kilogram of body mass needed to support growth decreases to 60 to 65 kcal.[2]

Daily exercise is important for skeletal growth, development, and appetite stimulation. Weanlings that are feed as a group should have ample feed space provided to prevent dominance by any one youngster. One can mix chopped hay with the grain to slow the feeding rate and increase the bulk, reducing the chance of grain engorgement and the risk of gastric dilation and rupture.[2,72] Individual feeding provides a greater opportunity for control of nutrient intake and supplementation when needed but is more labor intensive.

Overfeeding is a common problem in the management of growing horses. The reasons that young horses are overfed are, presumably, to enhance growth rate and, in the case of show horses, to give them a smoother appearance. Several studies comparing the growth of weanlings fed energy and protein levels as high as 150% to 200% greater than the 1979 NRC recommendations have been conducted,[73–76] but differences in design make them difficult to compare. The most consistent effect of overfeeding is an increase in average daily weight of 12% to 36%. Average daily gains in wither height have been reported not to differ[73,74] or to increase by 7% to 12%.[75,76] In summary, no advantage accrues from feeding a weanling in excess of its needs.

The DODs physitis, osteochondrosis, and contracted tendons frequently occur and are diagnosed just before or after weaning,[77–79] though the initiation of the defect probably occurs much earlier.[35] Diet analysis and correction of any imbalances or inadequacies is recommended as a conservative treatment to prevent further lesion development.[79]

5.4.4 YEARLINGS

Diets for yearlings should contain the same balance and fortification established in the weanling program (see Table 5-12). Growth rate continues to slow; weight gain has decreased to 0.5 kg/day, wither height to 0.04 cm/day. Yearlings have attained nearly 90% of their adult height by 12 months and 95% by 18 months. Overfeeding in preparation for sale or show may aggravate existing disease or result in conditions that may not be manifested in the short term[76] and therefore is not recommended. The presence of physitis, osteochondrosis, or cervical vertebral stenotic myelopathy is not uncommon in this age group.[78,80,81] With the exception of physitis, changes in the diet at this stage are not likely to improve clinical outcome but may arrest further lesion development and are recommended.[35]

5.5 Problems Related to Nutrition

5.5.1 OBESITY

Obesity in horses is a condition that currently is not recognized as a medical problem, is rarely treated, but is likely to have as major an effect on the health and longevity of horses as it does in other species.[82–84] To expect that excess condition in horses is just as likely to aggravate bone and joint injuries, reduce exercise tolerance, decrease heat tolerance, increase susceptibility to disease, and adversely affect reproductive performance would seem logical.

When is a horse considered to be obese? A person is considered to be obese whose body weight is 20% greater than the standard for height and frame; at 10% the person is simply overweight. No criteria for obesity have been established for horses as have been for dogs and cats.[84] Body condition scores of 6 to 9 describe horses with increasing degrees of fat deposition. In one study, an increase in body mass of 30 kg in a group of mares was associated with an elevation in condition score from moderately thin to fleshy.[17] The increase was only 6% of body weight, indicating that different criteria may be needed for the horse. One should use subjective appraisal by body condition scores and breed standards to provide a reasonable guide until more data are available.

The primary cause of obesity in horses is overfeeding or supplying calories in excess of use. Ponies, pleasure horses, and broodstock seem to be affected most often. Horses on lush pasture and with little exercise (i.e., broodmares) can become heavy; this situation is understandably difficult to control. Endocrine (i.e., hypothyroidism), metabolic, and genetic factors also may be involved.

With the exception of halter horses or market yearlings, feeding horses to an overweight or obese state is not intended. The problem and its treatment are a matter of dietary management rather than the dietary constituents per se. Some factors involved in obesity may be the following:

1. *Lack of knowledge concerning energy content of feeds and feed-weight-per-unit volume*. Few if any owners know the energy content of feedstuffs. Most can say that corn is higher in energy than oats but 250 251

cannot give the actual difference. This lack of knowledge is underscored further by the habit of feeding grain and hay by the convenient unit rather than weight: the scoop, coffee can, quart, and cup for grain and flake, section, and bat for hay, regardless of quality or type.

2. *Overestimation of maintenance needs*. Few owners know or have ever measured the weight of their horses. If the horse is one of the light breeds, the owner assumes it weighs 1000 lb and feeds it according to the recommendations for the 1000-lb reference horse at maintenance. As discussed previously, probably two levels of maintenance exist for most horses. The one referred to most often in feeding directions and textbooks has been discussed in the context of this chapter as field maintenance. For horses that spend a good deal of the time in stalls, feeding at this level may exceed their daily energy expenditure by as much as 30%.

3. *Inability to assess body condition*. Owners rarely admit that their horses are carrying more weight than is ideal and most are probably not sure how to know. Little emphasis is placed on the value or the "how to" of evaluating body condition in horses. For example, "hay bellies," more the result of poor-quality hay and little exercise, often are assumed to be a sign of obesity in horses, particularly young horses.

4. *Overestimation of exercise intensity*. An hour of leisurely trail riding at a walk and slow trot burns about 1 Mcal, resulting in minimal energy expenditure. Many owners feel this constitutes work and increase caloric intake. The presence of sweat often is viewed as evidence that the horse has worked hard, and owners may give extra feed to make up for this perceived increase in energy expenditure.

5. *Animal-human bond*. Like dogs and cats,[84] horses frequently are rewarded for compliance or their friendship by receiving feed: carrots, apples, horse treats, handfuls of grain, extra flakes of hay. Feeding establishes a direct relationship between owner and horse. The horse soon associates the presence of the owner with feed; the owner views the interest as affection and the relationship continues.

If one can find no medical cause for excessive weight gain, one should discuss treatment by dietary means with the owner. One should obtain the current weight and condition score of the horse. To encourage weight loss requires a reduction in calories below expenditure. A method the author has used with success begins with the formulation of a diet that provides 70% of the maintenance energy requirements of the horse *at its ideal weight*. Grass hay is suggested as the diet base because it is lower in digestible energy per kilogram than legume hay and also weighs approximately half as much per unit of volume as alfalfa hay, so one can feed more sections or flakes. This helps to reduce the concern of owners that they are starving their horses. One can supply vitamins and minerals by a supplement and trace mineral salt.

Exercise is an integral component of a weight loss program through stimulating the loss of fat rather than lean body mass, which may not be possible if the horse is lame or has respiratory compromise. Any increase in exercise, regardless of intensity, should be done slowly and monitored frequently.

Giving the owner some idea of how long the horse will take to reach its goal weight also is helpful. In most cases, the horse may take 3 to 5 months to reach goal weight. By the veterinarian's giving the owner an honest appraisal, the owner will know what to expect and will be more willing to comply. One should schedule periodic evaluations to monitor the progress of the horse. Once the horse has reached its goal weight, one can adjust the caloric intake for body maintenance and planned activity level.

5.5.2 DIARRHEA

This discussion is limited to common nutritional diarrheas in the horse. These diarrheas are usually more of a nuisance and unaesthetic than of clinical concern. No studies of their pathophysiology appear in the literature. Most likely, the diarrheas of dietary origin are osmotic and appear to result from an increase in carbohydrate fermentation and change in the microbial population. Osmotic diarrhea usually occurs when an excess of nonabsorbable, water-soluble, low-molecular-weight solutes is present in the bowel, drawing water into the gut. This type of diarrhea is usually self-limiting if the horse is given time to adapt to the change.

Sudden and large increases in grain intake can result in diarrhea in some horses. An increase in rate of passage presents a large quantity of partially digested and undigested carbohydrates to the colon, where the carbohydrates undergo rapid fermentation by the hindgut microflora. The rise in lactate and volatile fatty acid concentrations results in an increase in osmolality of the colonic fluid, causing an influx of water into the colon. If lactate production exceeds the buffering capacity of the colon, mucosal damage may occur, increasing toxin absorption. [85]

Fresh pasture is high in water and soluble carbohydrates. The loose, watery feces seen after horses are turned out to pasture likely are caused by a combination of the fermentation of the available carbohydrates, a more rapid rate of passage reducing water absorption, the high water content of the ingesta overwhelming absorptive capability, and the lack of long fiber to produce formed feces. 251

252

The soft feces that develop when some horses are fed alfalfa hay happens most often when an abrupt change has occurred from a grass hay to alfalfa hay or when the quality of the alfalfa hay has improved greatly. In this case the diarrhea probably is caused by the increased mineral content of alfalfa causing an osmotic diarrhea.[22] Fiber content also has decreased, reducing the dry matter content of the feces.

Show horses and racehorses frequently develop diarrhea during shipping or before performances. Although possibly caused by changes in feed and water, this diarrhea more likely is caused by stress, resulting in excessive stimulation of the parasympathetic nervous system, increasing gut motility and mucous secretion. However, the most common stress-induced diarrhea in horses is associated with *Salmonella* species (see Chapter 2).

5.5.3 COLIC

As with obesity, the nutritional causes and nutritional methods of prevention of colic are limited. In cases in which poor-quality or tainted feed is fed accidentally, colic may result, and one should caution the owner more about dietary management than about the diet itself. The horse evolved as a continuous grazer, consuming small meals frequently.[70] Most horses today are raised in confinement with little or no access to pasture and are fed high-concentrate meals according to schedules devised by the owner.[70,85] All too often not enough hay is given at stables, and water is not always clean and readily available. Without hay to keep their grazing instinct satisfied, horses may begin to eat wood or bedding or develop other vices such as weaving or cribbing to assuage boredom.[70,86] Only recently has evidence been provided to support the contention that current feeding practices alter physiologic responses and contribute to the occurrence of digestive upsets in the horse.[85]

Several ways exist to reduce the risk of some colics by dietary means. A discussion of the current practices with the owner or manager will help to identify those of most importance and narrow the focus.

1. Provide sufficient quantities of free-choice, good-quality, long-stem hay. Horses fed hay ad lib spend more time eating than horses fed pelleted feeds or all-grain diets.[86–88]
2. Increase the frequency of feeding and reduce the meal size.[85]
3. Avoid abrupt changes in hay or grain type or quantity.[1,85]
4. Avoid abrupt changes in times of feeding or order of feeding.[85]
5. Reduce the grain meal by half when the feeding schedule has been interrupted.
6. To slow the feeding rate, offer hay first to reduce the initial hunger urge.[1]
7. Provide plenty of clean, fresh, cool water.

5.5.4 DEVELOPMENTAL ORTHOPEDIC DISEASES

The DODs are conditions of the young, growing horse that occur with a disturbance in the conversion of cartilage to weight-bearing bone. Included in this group are osteochondrosis, osteochondritis dissecans (OCD) of cartilaginous origin, acquired angular limb deformities, physitis, subchondral cystic lesions, some cervical vertebral stenotic myelopathies, flexural deformities, and cuboidal bone malformations.[89]

Age at diagnosis is typically between birth and 2 years.[77,79,81] These diseases appear to occur predominantly in purebred horses, with Thoroughbreds, Quarter Horses, Standardbreds, and Arabians as the breeds most commonly affected.[89] Anecdotal and clinical data tend to support a higher incidence of OCD and cervical vertebral stenotic myelopathy in colts,[77,89] but the gender distribution for the other conditions has not been reported.

The etiologic profile of the DODs is complex. The factors most frequently implicated are (1) genetic predisposition, (2) rapid growth rate, (3) nutrition, (4) biomechanics and conformation, (5) trauma, and (6) metabolic function. Probably no one cause is the culprit, but rather a combination of all or some of these factors.

5.5.4.1 Genetic Predisposition

A growing body of evidence indicates that a heritable factor may be involved in some of these diseases.[90–93] A study of offspring produced by two wobbler stallions out of 12 wobbler mares did not result in neurologic lesions, but a high incidence of contracted tendons (30%), physitis (40%), and OCD (50%) was observed.[90] Radiographic screening of Standardbred trotting and Swedish Warmblood horses identified progeny from particular stallions that had a significantly ($P < 0.001$) higher frequency of OCD in the tibiotarsal joint than offspring of other stallions.[92] These observations have been confirmed by a more recent study in which the incidence of tibiotarsal osteochondrosis was as high as 30% for the progeny of two stallions.[93] The authors of the study point out that neither of these stallions had radiographic evidence of the disease, suggesting that progeny testing may be the best method of identifying genetically unsuitable broodstock.

5.5.4.2 Growth Rate

Energy and protein and the effects of overfeeding these nutrients on accelerating growth rate have long been implicated as the most likely cause of cartilage and bone disease in young horses,[77,94] but only anecdotal data exist.

Increases in energy and protein intake have resulted in greater weight gains compared with controls[75,76] but not compared with gains inferred from available growth data for young horses.[63,65–67,95] Acceleration of 252
vertical growth (wither height) by overfeeding has been less consistent.[73–76] Increased weight gains have been 253
associated with a higher occurrence of conformational defects in yearlings fed ad lib[76] and radiographic evidence suggesting physitis in weanlings[95] but do not appear to be related to contracted tendons[75] or to be necessary for the development of osteochondrosis.[35,91]

5.5.4.3 Nutrition

Several nutrients or dietary factors may be involved in DODs directly or indirectly. The balance and quantity of all dietary elements likely are critical for nutritional intervention.

5.5.4.3.1 Energy and Protein

Endocrine aberrations in response to the overfeeding of energy were implicated in studies in which starch intakes of 4.5 g/kg body mass were shown to result in a transient (60-minute) increase in postprandial circulating levels of triiodothyronine (T_3) and consequent decreases in thyroxine (T_4) concentration compared with starch intakes of 2.5 to 3.5 g/kg body mass.[96,97] Biochemical changes in normal-appearing cartilage from foals with dexamethasone-induced bone lesions[98] were presumed to be characteristic of OCD, and some similarities were found in cartilage from weanlings consuming high-starch diets.[73] Because T_4 is required for cartilage maturation, this led to the hypothesis that lesions of osteochondrosis may result from a high carbohydrate– induced hypothyroid state.[97] The hormones T_3 and T_4 have similar biologic effects.[99] Triiodothyronine has been shown to stimulate chondrocyte maturation and hypertrophy and increase alkaline phosphatase activity in porcine physeal cartilage.[100] Alkaline phosphatase secretion by matrix vesicles in the hypertrophic zone is considered a preparatory step in cartilage mineralization, though its precise role is unclear.[101,102] Therefore increases in T_3 would seem to accelerate cartilage maturation and endochondral ossification rather than retard it. Moreover, the concentrations of circulating T_3 and T_4 and insulin reported for the high-carbohydrate group were well within the normal range for horses between the ages of 4 months and 5 years.[103] One also should note that the weanlings in these studies received their entire caloric intake in two meals. The endocrine response seemingly would be different with the more standard management practice of continuous access to hay or pasture interspersed with two or three grain meals.

High dietary protein content has been linked with high energy in increasing growth rate[77] and has been reported to increase renal calcium excretion, resulting in negative calcium balance.[104] Increases in dietary

protein beyond the requirement in a later study did not increase gains in height or weight, nor were any detrimental effects on calcium absorption observed.[105]

5.5.4.3.2 Calcium and Phosphorus

The importance of calcium and phosphorus in proper bone formation is well known. Low dietary calcium or phosphorus can result in an excess of uncalcified bone and widening of the metaphyseal cartilage.[2] Nutritional secondary hyperparathyroidism, or bighead, and other skeletal abnormalities occur in the presence of low dietary calcium and adequate to high phosphorus.[106,107] Because calcium is absorbed primarily in the small intestine and phosphorus in the small and large intestines,[108] excess dietary phosphorus interferes with calcium by competing for the absorptive site. Physitis, once referred to as rickets, also has been linked to improper calcium and phosphorus balance,[78] though no scientific data prove the relationship.

Conversely, excess dietary calcium and hypercalcitonemia recently have been proposed to cause osteochondrosis in horses[109] based on data from an earlier overnutrition study in Great Dane puppies in which many nutrients (especially vitamin D) were excessive.[110] Studies have demonstrated that young ponies[108] and horses[111] respond to high calcium intake by decreasing intestinal absorption and increasing calcium excretion in the urine and feces and uptake by bone. No deleterious effects attributed to calcium have been noted at 2 times[35,75] to 5 times[112] the requirement when adequate phosphorus (ratio of at least 2:1) was present.

High calcium per se is unlikely to be responsible for DOD, but one should consider its effect on other nutrients. Alfalfa is becoming the predominant forage fed to horses.[1] The calcium content of alfalfa can be between 2 and 10 times higher than that of grass or mixed hay.[2] If alfalfa hay is fed with commercial feeds designed for grass hay, a higher-than-desirable intake of calcium could result[113] and be of concern in the presence of high dietary vitamin D. Excess dietary calcium can interfere with the absorption of zinc[114–116] and manganese,[117] two trace elements that are co-factors in cartilage metabolism.

5.5.4.3.3 Trace Minerals

Low dietary concentrations of copper, manganese, or zinc have been shown to result in cartilage and bone abnormalities in several species,[118–123] including the horse.[35,68,124] The primary roles of these minerals are as constituents of metalloenzymes involved in cartilage synthesis or calcification.[119,121,125]

As early as 1946, copper supplementation was shown to prevent the development of angular limb deformities and articular surface erosions in young show calves.[126] In 1949, articular cartilage defects were observed in normally growing foals fed diets containing 8 ppm copper but not in diets containing 18 ppm copper.[127] The relationship between copper and cartilage abnormalities in foals was supported further by
reports of a copper-responsive osteodysgenesis[128,129] and the presence of severe cartilage ulcerations in 253
hypocupremic foals.[124] Subsequently, copper supplementation to mares in late gestation and to their foals 254
was found significantly to reduce the number and type of cartilage lesions in the foals compared with the number of lesions in foals that along with their dams had been fed diets containing copper concentrations according to the NRC recommendation.[35] Although copper is well known as a component of lysyl oxidase,

the enzyme responsible for the cross-linking of hydroxylysyl residues in collagen synthesis,[130] the mechanism of the apparent effect of copper is not known. Possibly, other biochemical roles for copper in cartilage synthesis and calcification remain to be identified. A 1993 study[68] that should prompt further investigation described biochemical changes in the cartilage of foals fed low-copper diets.

Manganese deficiency causes enlarged joints and perosis in growing chicks.[121,131] The primary cartilage defect in chicks appears to result from a decrease in proteoglycan synthesis caused by a lack of glycosyltransferases, manganese-containing metalloenzymes.[121] Angular limb deformities, congenital fractures, and tendon contractures in foals have been associated with low manganese concentrations in pastures, but the precise biochemical or structural cause was not identified.[132,133]

A decrease in osteoblastic activity with an increase in cartilage matrix was observed in chicks given zinc-deficient diets.[119] Consequently, the activity of alkaline phosphatase, a zinc metalloenzyme, was shown to be reduced in zinc deficiencies.[134] Alkaline phosphatase concentration and activity are high in the resting zone and in matrix vesicles of the zone of hypertrophy.[101,135] Though initially its primary role of alkaline phosphatase was thought to be via the hydrolysis of pyrophosphate, an inhibitor of cartilage calcification,[136] alkaline phosphatase activity now appears to be diverse in cartilage matrix, cleaving a variety of phosphate-containing substances crucial to the initiation of calcification.[101,102]

Most feedstuffs are inherently low in zinc, with an average concentration of 20 to 25 ppm.[2] This concentration is less than the NRC dietary recommendation of 40 ppm. Moreover, the presence of dietary antagonists may further inhibit absorption. Soybean meal frequently is used as the protein source in diets for young horses.[1,2] Bean and seed meals are known to contain high levels of phytate, which has been shown to interfere with zinc availability, particularly in the presence of high calcium concentrations.[114,116] This antagonism could be of concern with forages high in calcium, such as legumes.

5.5.4.4 Biomechanics and Conformation

Excessive compression of growth plates has been shown to result in focal areas of cartilage thickening and, when severe and prolonged, eventual thinning, premature vascular invasion, and closure of the plate.[137,138] When the compression was removed, mineralization and calcification were restored. The primary lesions are believed to have resulted from a cessation of blood flow to the cartilage, reducing nutrient delivery. The focal, cone-shaped thickenings observed in rabbit cartilage undergoing compression have been reported in metaphyseal cartilage of foals and weanlings,[35,139] but their pathologic significance in young horses is not known.

Young horses that are heavily muscled, carrying excess condition, and have some degree of limb malalignment seem to be more prone to develop the firm, metaphyseal enlargement of the distal radius, metacarpus, or metatarsus referred to as physitis.[78,95,140,141] Foals that are toed in with offset knees also seem more vulnerable.[140] Thinning of physeal cartilage with columnar disorganization and the formation of bone bridges has been associated with epiphyseal compression and the formation of exostoses in young horses with clinical evidence of physitis.[141]

5.5.4.5

Trauma

Any damage that compromises vascular penetration and nutrient delivery affects cartilage growth and maturation. Trauma is likely to be responsible for the separation of defective tissue, as in osteochondritis dissecans, but is not believed to be the primary cause.[142] For trauma to account for a majority of the cases of DOD seems unlikely, but one cannot overlook trauma as a cause.

5.5.4.6

Metabolic Function

Cartilage growth and endochondral ossification are orchestrated by the initial or subsequent release of several hormones. Growth hormone, somatomedin C, insulin, T_4, parathyroid hormone, calcitonin, vitamin D, estrogen, and testosterone can stimulate or suppress chondrocyte proliferation, sulfate incorporation, proteoglycan synthesis, or calcification.[135,143] In hypothyroid foals, evidence of faulty endochondral ossification such as osteochondrosis, delayed physeal closure, and ossification of the carpal and tarsal bones has been described.[144,145]

5.6

Nutritional Support of the Sick Horse

Interest in the development of nutritional support protocols for the hospitalized veterinary patient continues to grow. The adverse effects of inadequate nutritional support are well documented and may be a contributing factor to poor response of traditional therapies. Early, aggressive nutritional intervention of critically ill or injured patients helps to prevent unnecessary depletion of nutrient stores, promote repair, reduce the number and severity of secondary complications, improve the response to antibiotic treatment, and increase the chances of a favorable outcome. 254

255

5.6.1

METABOLIC CONSEQUENCES OF STARVATION VERSUS DISEASE

Recognizing the differences in the metabolic response of the body to starvation and to disease is critical for understanding the importance of nutritional intervention. In starvation the goal of the body is to economize, to do what is necessary to lengthen life in the face of low or no food supplies. The decrease in circulating insulin following food deprivation results in a reduction of the conversion of T_4 to T_3, lowering the metabolic rate and reducing energy expenditure. Glucagon is released in response to the hypoglycemia, triggering hepatic glycogenolysis to supply the needed glucose. This source is depleted quickly, making amino acids from body protein the predominant sources of glucose in the early phase of starvation. Fats also are mobilized as energy sources, producing fatty acids and glycerol. In the starving horse, most of the fatty acids and glycerol are reesterified to triglycerides and transported out as very-low-density lipoprotein (VLDL).[146] Analysis of the composition of VLDL produced in the fasted state show that it is higher in cholesterol and lower in protein than the VLDL in fed ponies[147] and may explain the hypercholesterolemia observed during fasting. The VLDL is transported to the peripheral tissues where it is cleaved by membrane-bound lipoprotein lipase, providing free fatty acids as energy substrates. Some of the glycerol is used for glucose production, and fatty acids channeled for ketone production can be used by brain and heart as an alternative energy source, sparing glucose and ultimately body protein. When this occurs, stored body fat becomes the main source of fuel, though protein losses still continue at a slower rate. Other effects of starvation include (1) decreased synthesis of albumin, transferrin, and fibrinogen; (2) shrinking of the intestinal villi and decreased digestive enzyme synthesis and

activity; (3) depression of immune response mechanisms, including antibody synthesis, phagocytosis, and neutrophil activation; and (4) muscle atrophy and weakness from continued degradation of muscle protein. Once fat stores have been depleted, protein becomes the primary fuel source. Continued protein degradation results in multiple organ failure and ultimately death.

The response of the body to stress is much different than is its response to starvation. The attempt to conserve is reversed in the presence of trauma and disease. D.P. Cuthbertson[148] has described the response to stress in two phases: the “ebb” phase and the “flow” phase. The ebb phase is characterized as the period immediately following injury when a decrease occurs in peripheral vascular perfusion, cardiac instability, and hypometabolism. Once resuscitation has been successful and perfusion has been restored, the hypermetabolism, amino acid mobilization from skeletal muscle, and significant increases in gluconeogenesis associated with the flow phase of the stress response begin. Several hormones act as key effectors in the flow phase. Catecholamines are released in response to stress, causing an increase in the metabolic rate and the β-adrenergic–stimulated release of glucagon to elevate glucose production. A rise in adrenocorticotropic hormone also occurs, promoting a subsequent increase in glucocorticoid secretion and providing an additional stimulus for glucagon, continuing to drive amino acid mobilization from skeletal muscle and lipolysis. Tumor necrosis factor and interleukin-1, two of several cytokines produced by T cells and macrophages during the acute phase response, initiate the induction of fever by a direct effect on the hypothalamus, thereby increasing energy expenditure approximately 7% for every degree Fahrenheit rise in body temperature. Hyperglycemia frequently is observed in septic patients in the face of normal or increased insulin secretion, possibly because of a combination of cortisol-driven gluconeogenesis and an increased peripheral insulin resistance.[149] Additional demands for glucose and amino acids also are incurred for tissue repair and acute phase protein synthesis. Without protein and energy intake to ameliorate some of the loss, functions such as wound healing and host defense may be sacrificed to support tissues of highest priority for sustaining life.

5.6.2 ENTERAL FEEDING

5.6.2.1 Candidates for Nutritional Support

Not all patients require enteral nutritional support. Most horses that were well nourished before the onset of acute, short-term disease resume eating within a short period (3 to 4 days). However, for the disease process of some horses to worsen is not uncommon, prolonging the inappetence and initiating the catabolic state described previously. The criteria of Butterworth,[150] modified for horses and listed in Boxes 5-2 and 5-3, are suggested to help identify likely candidates for nutritional support.

Horses that have been anorectic for more than 3 days generally are normo- or hypoglycemic, hypertriglyceridemic, hypercholesterolemic, and hyperbilirubinemic (Table 5-14). Though hypertriglyceridemic horses are usually hypophagic, the converse is not always true. The appearance of opaque sera suggests hyperlipemia, a serious condition requiring immediate medical and nutritional intervention. Azotemia may or may not be present but may exacerbate the development of hyperlipemia.[151] Horses that have been ill for some time often have low packed cell volumes but normal mean corpuscular hemoglobin concentrations and mean corpuscular volumes, indicating the anemia of inflammatory disease.[152]

If one has no reason to suspect that the absorptive capacity of the digestive tract has been reduced, one should 255
choose enteral feeding. This route is the most physiologic and the simplest, easiest, safest, and least expensive 256
method of providing nutritional support.

5.6.2.1.1

BOX 5-2 FEATURES OF THE PHYSICAL EXAMINATION SUGGESTING POOR NUTRITIONAL STATUS

1. Cutaneous
   a. Thin, shiny skin
   b. Drying and scaling of skin
   c. Easily pluckable hair
   d. Decubitus ulcers
   e. Follicular hyperkeratosis
   f. Nonhealing surgical wounds
2. Mucous membranes
   a. Pallor or redness of buccal mucosa, gums
   b. Atrophy of lingual papillae
3. Musculoskeletal and neurologic
   a. Joint laxity
   b. Physitis
   c. Growth retardation
   d. Flexural deformities (<1 yr old)
   e. Weakness and atrophy
   f. Ataxia
4. Abdominal and other organs
   a. Hepatomegaly
   b. Ascites
   c. Small bowel distention, gas or fluid
   d. Lymphadenopathy, tumors
5. General appearance
   a. Edema
   b. Obesity

c. Cachectic appearance

Modified from Butterworth CE Jr: Some clinical manifestations of nutritional deficiency in hospitalized patients. In *Proceedings of the second Ross Conference on Medical Research: Nutritional Assessment—Present Status, Future Directions and Prospect,* Columbus, Ohio, 1981, Ross Laboratories.

5.6.2.2

Nutritional Formulae

The first “blenderized” enteral diet for hospitalized horses, pioneered by Naylor, Freeman, and Kronfeld[153] (Table 5-15), provided clinicians with a means by which to meet the energy and protein needs of their equine patients. Unfortunately, this diet and other home brews are not only difficult to procure, mix, deliver, and store but often can be energy-dilute because of the large volume of water needed to deliver them, and they may lack nutritional balance and adequacy. Since then, other diets for enteral feeding have been tested or developed. Pelleted horse feeds designed to supply the grain and forage components of the diet generally are used as the base for slurries.[154] These feeds have the advantage of being nutritionally balanced, less expensive, and widely available compared with the alfalfa-casein-dextrose mixture. The pelleted feed chosen should be age- and nutrient-appropriate for the horse. One also can tailor these diets to meet specific needs. To increase energy density, one may add vegetable oil. One may increase protein content by adding alfalfa meal, finely ground soybean meal, or a modular component used for human liquid diets. Adding raw eggs to increase protein is not advised because of the risk of salmonella contamination. As with the Naylor diet, large volumes of water are needed to reduce viscosity for hand pumping or funneling via tube.

5.6.2.2.1

BOX 5-3 FEATURES OF THE CLINICAL HISTORY SUGGESTING NUTRITIONAL RISK

1. Recent weight loss of 10% or more of usual body weight
2. Restricted oral intake of nutrients or intravenous infusions of simple solutions only for the preceding 10 days or more
3. Protracted nutrient losses resulting from the following:
    a. Diarrhea, malabsorption syndromes
    b. Surgical absence of portions of the gastrointestinal tract
    c. Draining fistulae, abscesses, wounds, burns
4. Increased metabolic needs because of the following:
    a. Extensive burns, infection, trauma
    b. Fever
    c. Lactation, recent pregnancy, recent surgery or trauma
5. Use of drugs with antinutrient or catabolic properties, such as the following:

   a. Corticosteroids
   b. Immunosuppressants
   c. Antitumor agents
   d. Miscellaneous (e.g., antibiotics, antacids, anticonvulsants)
6. Chronic disease or impaired function of any major organ system

Modified from Butterworth CE Jr: Some clinical manifestations of nutritional deficiency in hospitalized patients. In *Proceedings of the second Ross Conference on Medical Research: Nutritional Assessment—Present Status, Future Directions and Prospects,* Columbus, Ohio, 1981, Ross Laboratories.

Commercially available liquid diets fed to hospitalized human patients also have been used successfully as the sole source of nutritional support in a variety of clinical cases.[155,156,156a,156b] Proteins of high quality such as 256
casein, whey, or soy protein isolate are used most frequently as the protein source. The fat sources are all 257
vegetable. Many formulae contain a combination of one or more of the vegetable oils with medium-chain triglycerides, which are prepared from the fractionation of coconut oil and are 6 to 10 carbons long.[157] Medium-chain triglycerides are more water soluble, requiring little lipase activity or conjugation to bile salts for absorption to occur. Medium-chain triglycerides are hydrolyzed more rapidly than long-chain triglycerides and are transported directly into the blood via the portal system, making them a readily available energy source.[155] The carbohydrate sources are primarily starch hydrolysates (e.g., maltodextrins and oligosaccharides), which are absorbed rapidly, and because they are more complex, they help to reduce osmotic load. Because these formulae were designed to meet the nutrient needs of human beings, they do not meet all of the vitamin and mineral requirements of the horse and should not be used for long-term feeding. As a direct result of these efforts, an enteral formula designed exclusively for use in horses recently has become available (NutriPrime, KenVet, Ashland, Ohio). Though the cost per day for these liquid diets is higher than conventional slurries, the complete nutrient profile, consistent nutrient composition, ease of administration, and sterile packaging are noteworthy advantages. Tables 5-16, 5-17, and 5-18 give the ingredients and nutritional composition of some of the prepared formulae, including the equine diet.

TABLE 5-14 Some Reported Serum Chemistry Changes in Fed, Fasted, and Sick Horses

			SICK	
MEASUREMENT	FED	FASTED (88 HOURS)	ANORECTIC	HYPERLIPEMIC
Triglycerides, mg/dl	23 ± 7	160 ± 50	158 ± 66	1567 ± 972
Free fatty acids, mg/dl	0.5 ± 0.5	23 ± 10	—	23 ± 8

Dehydrated alfalfa meal, g	2000	2000	2000	2000	2000	2000	2000
Energy, Mcal[§]	7.4	8.4	9.4	10.4	11.8	11.8	12.2

From Naylor JM, Freeman DE, Kronfield DS: Alimentation of hypophagic horses, *Compend Cont Educ Pract Vet* 6:S93, 1984.

* These allowances should be divided and administered in three feedings daily. Maintenance requirements for a 450-kg horse are 13 Mcal of digestible energy and 580 mg crude protein.

† Ten g NaCl, 15 g NaHC03, 75 g KCl, 60 g K_2HPO_4, 45 g $CaCl_2 + 2H_20$, and 25 g MgO.

‡ Dehydrated cottage cheese: 82% crude protein with less than 2% lactose (American Nutritional Laboratory, St. Louis, Mo.) or casein (Sigma Chemical, St. Louis, Mo.).

§ Megacalories of digestible energy.

5.6.2.3 Nutrient Requirements

The purpose of enteral support is to provide the necessary nutrients for maintenance and healing until the horse can obtain sufficient quantities by voluntary oral intake. Though the specific nutrient needs of the sick horse are not known, data pooled from human and animal studies have provided reasonable estimates for use 257
in equine cases. The basal energy requirement rather than that for resting maintenance is the foundation for 258
calculating the energy expenditure in sick human beings and animals. Horses requiring medical attention are generally at stall rest in a controlled environment, reducing the energy need for physical activity and thermoregulation. One can calculate the resting energy requirement of horses in stalls from the formula 21 kcal(BM_{kg}) + 975 kcal.[15] This product is roughly 70% of that needed for field maintenance, equal to 11 Mcal/day for a 500-kg horse. The basal energy requirement is but one part of the resting energy value. Another significant component is the heat of fermentation produced by microbial action in the hindgut. When feed intake decreases, the substrate available for the microbes decreases, reducing substrate turnover. Microbial fermentation gradually decreases and less heat is produced. The energy for digestion, absorption, and product formation also have decreased, lowering energy losses even further. Therefore the actual energy requirement of the horse at rest may be closer to 55% to 60% of field maintenance. Until more data are available, the increases in energy expenditure resulting from illness or injury are applied to the resting energy estimate through the use of injury factors (Table 5-19). If more than one factor is involved, one should use the highest multiplier.

TABLE 5-16 Total Feed Required per Day to Meet Maintenance Requirements of a 500-kg Adult Horse

INGREDIENT	AMOUNT/RECIPE	×	NO. RECIPES NEEDED/DAY	=	TOTAL INGREDIENTS NEEDED/DAY
Alfalfa/casein/dextrose slurry					
Alfalfa meal	454 g	×	5.9	=	2679 g alfalfa meal
Casein	204 g	×	5.9	=	1204 g casein
Dextrose	204 g	×	5.9	=	1204 g dextrose
Electrolyte mixture	52 g	×	5.9	=	307 g electrolyte mixture
Water	5 L	×	5.9	=	30 L water
Pellet/vegetable oil slurry					
Complete pelleted horse feed	454 g	×	10.7	=	4860 g complete pellet
Corn oil	46 g	×	10.7	=	492 g (535 ml) corn oil
Water	3 L	×	10.7	=	32 L water

Nitrogen balance studies have been used to determine the protein needs of hospitalized human patients.[158,159] Protein catabolism increases dramatically, with nitrogen losses in burned and septic patients increasing by nearly 250%. Without sufficient protein or caloric intake, protein is metabolized for energy instead of being used for protein synthesis and repletion. One therefore uses the calories-to-nitrogen (Cal/N) or nonprotein calories- to-nitrogen (NPCal/N) ratio to estimate the protein requirement. A Cal/N ratio between 130:1 and 180:1 or an NPCal/N ratio between 100:1 and 150:1 is considered optimal for most stressed human patients.[159] The lower ratios are recommended for septic or severely traumatized patients. Until more data are available, these ratios seem reasonable for sick horses as well. For practical purposes, one should provide 5 g protein for every 100 kcal.

TABLE 5-17 Quantity of Diets Required per Day to Meet Daily Energy Requirement*

DIET	ENERGY REQUIRED	ENERGY PER RECIPE OR LITER OF DIET	RECIPES OR LITERS NEEDED PER DAY
Alfalfa/casein/dextrose slurry	16.4 Mcal	2.77 Mcal/recipe	16.4/2.77 = 5.9 recipes
Pellet/vegetable oil slurry	16.4 Mcal	1.53 Mcal/recipe	16.4/1.53 = 10.7 recipes
Osmolite HN	16.4 Mcal	1.06 Mcal/L	16.4/1.06 = 15.5 L
EquiCal	16.4 Mcal	1.00 Mcal/L	16.4/1.00 = 16.4 L

* Daily energy requirement for a 500-kg adult horse is 16.4 Mcal of digestible energy.

Increases in vitamin and mineral needs above those needed for maintenance do not appear to be necessary unless drug-nutrient interactions affect micronutrient status.

5.6.2.4 Method of Delivery

Feeding solutions generally are delivered by gravity flow or by hand pump. Nasogastric intubation or cervical esophagostomy are the preferred routes.[160] As with liquid diets, the soft pouches and gravity feeding sets developed for human hospitals have been relatively easy to adapt for veterinary use.[156] 258

TABLE 5-18 Nutrient Profile of Enteral Diets Supplying Daily Maintenance Energy Requirements for a 500-kg Adult Horse

NUTRIENT	REQUIREMENTS*	ALFALFA/CASEIN/DEXTROSE SLURRY	PELLET/VEGETABLE OIL SLURRY	OSMOLITE HN†	EQUICAL‡

Nasogastric tubes for enteral support of mature horses are generally 200 to 250 cm (80 to 100 inches) long. The internal diameter should not be less than 14F to obtain a reasonable flow rate. One should place tubes in the stomach or in the distal esophagus. Gastric reflux is more likely to occur when large-bore tubes are passed into the stomach.[158] One should secure the tube to the halter or, in the case of esophagostomy, tape it to the neck. A muzzle may be necessary to prevent the horse from dislodging the tube. One should remove the tube before the reintroduction of solid food because it may double back into the oral cavity where it can be chewed in half.

Large-bore, thick-walled rubber and polyvinyl chloride (Tygon) stomach tubes used for drenching and gastric decompression commonly are used. One drawback, however, is that they become stiff and brittle when exposed to digestive fluids. Local irritation and ulceration of the nasal septum, larynx, and pharynx are also a major concern when these tubes are left in place. The smaller bore (6 to 8 mm internal diameter) versions of these tubes have been used for short-term support but suffer from excess pliability, making them difficult to place and subject to kinking.

TABLE 5-19 Activity and Injury Formulae Suggested for Use in Horses

ACTIVITY		INJURY	
Stall rest	1.2 × REE*	Minor trauma or surgery	1.3 × REE
Walking, grazing	1.7 × REE	Skeletal trauma	1.3–1.4 × REE
		Sepsis, cancer	1.5–1.7 × REE
		Major burn	1.7–2.0 × REE

Modified from Long CL, Schaffel N, Geiger JW et al: Metabolic response to injury and illness: estimation of energy and protein needs from indirect calorimetry and nitrogen balance, *JPEN J Parenter Enteral Nutr* 3:452, 1979.

* REE (resting energy expenditure) = 21 kcal (BM_{kg}) + 975 kcal.

Polyurethane and silicone tubes dominate the human enteral tube market. These materials offer several advantages in that they are softer, less irritating, and do not harden. Most are also radiopaque. Silicone stomach tubes designed for horses are available (BIVONA, Inc., Gary, Indiana) but are rather large and thick-walled, making flow rate difficult to control. A polyurethane, 18F, 98-inch enteral feeding tube for adult horses is currently available (KenVet).

5.6.2.5

Rate of Delivery

Bolus delivery, or the rapid administration of formula by hand pump or syringe, is used most often. Although this method certainly saves time, it can result in diarrhea, abdominal pain, and distention, especially during the period of diet introduction.

Continuous and intermittent feeding become more popular as the use of enteral support increases. In intermittent feeding, a prescribed volume is infused by gravity drip over a longer period of time (60 to 120 minutes) at set intervals (every 2 or 3 hours) rather than continuously. Many of the complications that occur with bolus feeding in human beings have been reduced by slower and more controlled rates of delivery.

5.6.2.6

Guidelines for Feeding the Sick Horse

The following are guidelines for feeding sick horses:

1. Hydrate the horse adequately and correct any electrolyte or acid-base abnormalities before initiating enteral feeding. 259

260

2. Estimate the energy needs of the horse using the *current* body weight rather than the ideal body weight. The *initial* goal is to prevent further weight loss. Estimate protein needs.
3. Select the formula or slurry to be used and calculate the volume needed to meet the energy needs. Extra protein, if needed, can be added with protein modules (i.e., ProMod, Ross Laboratories, Columbus, Ohio; Casec, Mead Johnson Nutritionals, Evansville, Indiana).

4. Design the feeding schedule such that the maximum volume per feeding when the full-volume goal is reached is 3 to 4 qt. A minimum of four to six feedings usually is required. Tolerance is best when small feedings are delivered frequently.

5. Place the stomach tube or indwelling nasogastric tube. Verify the proper position of the tube before each feeding. Horses must remain standing or in sternal recumbency during feeding to prevent reflux and aspiration.

6. Some horses may need to be brought up to full-volume feeding slowly. For young horses, postoperative cases, or horses that have been anorectic for 5 days or more, feed 25% of the full-feeding volume on the first day. Increase to 50% on the second or third day and then to 75% if tolerance has been acceptable. Though energy needs have been estimated, the actual calories needed to maintain body weight vary from horse to horse. Some may maintain their weight when fed at 75% of the calculated full-feeding volume. If this occurs, no further increases in formula volume may be needed. Otherwise, increase to 100% as dictated by body weight and tolerance.

7. Flush the tube with warm water *before feeding* to verify placement and patency and *after feeding* to rinse out formula and prevent clogging. If the tube cannot be flushed, formula exits from the nostril, or the horse is in distress, do not feed.

8. Feeding volumes of 3 to 4 qt have been delivered by bolus safely over 10 to 15 minutes. Slower rates (feeding over 30 to 60 minutes) are recommended during the adaptation period to reduce the risk of intolerance.

9. Between feedings, muzzle horses to prevent removal of the tube but allow for free-choice water consumption.

10. Feces production and volume varies depending on the diet used. Loose feces are not uncommon and are of little concern if not accompanied by other signs of organic disease. The liquid enteral preparations are low-residue diets, resulting in small, soft fecal balls with mucus of low frequency and volume. If the horse becomes depressed, febrile, colicky, or dehydrated, stop feeding.

11. Continuous or intermittent gravity drip of liquid enteral formula is strongly recommended for horses that may have reduced absorptive capability (i.e., prolonged inappetence or humane rescues). In some of these horses, a combination of enteral and parenteral support may be most effective until gastrointestinal function is restored.

5.6.2.7 Clinical Monitoring

One should review laboratory work as needed to monitor clinical status. No definitive indexes are available to assess the quality of nutritional intervention in horses. Serum triglycerides, cholesterol, and bilirubin generally respond quickly to refeeding, falling back to within normal ranges in 24 to 48 hours. Because of the peripheral insulin resistance that occurs in hypermetabolic states, one should monitor blood glucose concentration closely in the early stages for the development of hyperglycemia. In this instance, one should decrease formula volume to reduce glucose intake.

5.6.2.8 Reintroduction of Solid Feed

Once the disease process has been brought under control, most horses begin to show interest in hay and grain. Energy formerly used for battling disease is rechanneled to support increased voluntary activity, resulting in little if any change in estimates for energy need. The initial goal, however, is merely to substitute the enteral formula for solid feeds before implementing any increases in energy intake. As recommended for any feeding program, one should add these proprietary feeds gradually to allow the digestive tract time to adjust to the “new” substrates. Using feeds with which the horse is familiar further encourages eating. One should select hay that is leafy and has a fresh aroma to encourage consumption. The type of hay is not critical, though alfalfa tends to be higher in leaf content and therefore higher in energy and protein than most grass hays or clover hay. One should begin by offering 3 to 5 lb/day for the first 3 to 4 days, reducing the amount of enteral formula by roughly 1 qt for every pound of hay consumed. One should add grain only when hay alone cannot meet energy needs. If lean body mass has decreased, repletion by increasing energy intake above the requirement with no increase in muscular activity results in the deposition of fat instead of muscle. Repletion of all nutrients is accomplished best gradually.

5.6.2.9 Drug-Nutrient Interactions

Drugs commonly used in veterinary medicine can have a profound effect on the nutritional status of the animal through suppression of appetite or by a direct pharmacologic effect. This is not to suggest that one 260
should question the use of drugs thay may affect nutritional status, but a more thorough understanding of their 261
interactions will assist the clinician in addressing the nutritional needs of the patient more accurately.

Several drugs have been shown to affect the senses of taste and smell in human beings. If this also occurs in horses, many horses may refuse to consume feeds that are normal constituents of their diet. Table 5-20 lists the drugs commonly used in equine medicine and the effects that these drugs have been reported to have in human patients.

When should one administer medications to horses that are tube fed? Because most pharmacologic data suggest that absorption occurs most rapidly in the fasted state, the recommendation that drugs be given 2 hours before or 2 hours after a feeding seems appropriate. Using liquid preparations of certain drugs when available rather than grinding or crushing tablets for administration prevents clogging of the tube, necessitating tube removal and replacement.

TABLE 5-20 Drug-Nutrient Interactions Reported in Human Beings

DRUG	GASTROINTESTINAL INTERACTIONS	METABOLIC INTERACTIONS	LABORATORY VALUES*
Amikacin sulfate		Anorexia, polydipsia, salivation	↑ BUN, creatinine
Amoxicillin	Diarrhea	Anemia; affects taste	↑ AST
Ampicillin			↑ AST, ALT
Cimetidine (Tagamet)	Diarrhea, gastric secretion		↑ Creatinine, AST, ALT, ALP
Erythromycin	Diarrhea, cramps	Jaundice	↑ ALP, bilirubin, AST, ALT
Betamethasone valerate-gentamicin sulfate (Gentocin)		Anorexia, polydipsia	↑ BUN, AST, ALT, LDH, bilirubin, creatinine
Metoclopramide (Reglan)	Diarrhea		↓ Mg, Na, K, Ca
Metronidazole (Flagyl)	Diarrhea, epigastric distress	Anorexia; alters taste ↓ Bacterial synthesis of vitamin K	
Moxalactam			↑ AST, ALT, BUN, creatinine, ALP
Penicillin G procaine, penicillin G benzathine	Diarrhea, gastritis	Alters taste; anorexia	
Pyrimethamine (Daraprim)		Interferes with folate metabolism; anorexia	
Ranitidine (Zantac)	Constipation, abdominal pain		
Rifampin	Epigastric distress, cramps, diarrhea	Anorexia; alters taste	↑ AST, ALT, GGT, creatinine
Sucralfate (Carafate)	↓ Absorption of vitamins A, D, E, and K; constipation	Anorexia	↑ AST, ALP, BUN, bilirubin, uric acid
Sulfamethoxazole-trimethoprim (Bactrim)	Diarrhea, ↓ absorption of folate and vitamin K		↑ Creatinine, BUN, AST, ALT, bilirubin
Tetracycline	↓ Absorption of Ca, Fe, Mg, Zn, and amino acids; diarrhea	Anorexia, ↓ vitamin K synthesis by bacteria	↑ ALP, BUN, bilirubin, AST, ALT

* *AST,* Aspartate aminotransferase; *ALT,* alanine aminotransferase; *ALP,* alkaline phosphatase; *BUN,* blood urea nitrogen; *LDH,* lactate *GGT,* γ-glutamyltransferase.

5.6.2.10

Complications of Enteral Feeding

Aspiration of formula into the lungs can be one of the most serious complications of enteral feeding. Verification of tube placement before and after each feeding, checking for gastric residuals before feeding, and

ensuring that the head and neck are raised during administration of the diet are advisable. If one obtains a gastric residual volume equal to or greater than 50% of the normal feeding volume, one should withhold the feeding and should evaluate the cause of the decrease in gastric emptying. Gastric emptying rates are reduced in sepsis, peritonitis, or following abdominal surgery.[161] Certain drugs also may reduce the gastric emptying rate.

Because the composition of most enteral formulae makes them ideal growth media for bacteria, care in preparation and handling is essential. Though not a major cause of clinical problems in the human hospital setting, secondary infections attributable to bacterial contamination of formula have been reported.[162,163] 261
Many bacteria have been isolated, including *Escherichia coli, Enterobacter, Klebsiella,* and *Salmonella.* 262
Sterile commercial preparations can be contaminated at mixing or from the hospital environment and many home brews may be contaminated inherently. To reduce this risk, one should prepare the formula in a reasonably clean environment and administer it as soon as possible after preparation. One should prepare only enough formula for one feeding if feeding a bolus; one should not mix a 12- to 24-hour quantity, even if it is to be stored refigerated. One should thoroughly wash and rinse all utensils. One should rinse enteral feeding bags and administration sets until the wash solution is clear and should disposed of them after 24 to 48 hours.

Gastrointestinal complications such as bloating, colic, and diarrhea can occur during the first few days of enteral feeding and can have a variety of causes: an adaptation period that is too short; bolus feeding; rapid administration; large, infrequent feedings; carbohydrate intolerance; or a nondietary cause such as antibiotic therapy. One generally can avoid these complications by taking a conservative approach to enteral feeding, developing a reasonable adaptation schedule to guarantee compliance, feeding small volumes slowly and frequently, and returning to a previously tolerated rate and volume until tolerance is reestablished. The commonly encountered, antibiotic-induced diarrhea usually resolves quickly once the drugs are discontinued. However, if the microfloral population has been reduced significantly, additional time may be needed for these microbes to become reestablished.

5.6.2.11 Parenteral Support

Parenteral nutrition is the administration of nutrients by intravenous infusion. If desired, one can supply all of the nutritional needs of the horse by the intravenous route. The goals of parenteral support are the same as those for enteral support: providing energy and protein to prevent catabolism of body protein and to promote repair. This method of nutritional support is of value when use of the gastrointestinal tract is contraindicated for more than 5 to 7 days. Lack of access to the gastrointestinal tract (e.g., pharyngeal obstruction), severe diarrhea, malnutrition, massive small bowel resection, intestinal obstruction or prolonged ileus, continual gastric reflux, and a high risk of aspiration are situations when parenteral support is appropriate.[164] As with human patients, one must make the decision to use parenteral nutrition carefully case by case because of the expense, time, and expertise required for mixing, administering, and monitoring and because of the potential risks involved.[165] However, knowledge of the potential complications and their causes, careful monitoring, and prompt treatment by attentive, dedicated staff have made parenteral nutrition a successful adjunct to veterinary care.

5.6.2.11.1 Admixtures

Admixtures used in parenteral nutrition generally are composed of sterile solutions of dextrose, amino acids, and electrolytes. One also can add fat in the form of a lipid emulsion if greater caloric density is needed. Like enteral solutions, these mixtures are ideal growth media for bacteria and must be used within

12 hours or less after mixing. To prevent contamination, one should mix solutions using aseptic techniques in a designated area, preferably with a laminar flow hood. If one must store solutions after final mixing, one should refrigerate them immediately and use them within 12 to 24 hours.

Dextrose (glucose) is the carbohydrate used in most, if not all, parenteral mixtures. To increase the caloric density, several concentrations of dextrose are available, but one must take care because of the hypertonicity of such solutions. Fifty percent dextrose solutions are used most often in equine parenteral support, with an osmolarity of 2525 mOsm/L. For most standard formulae, the dextrose concentration should not exceed 30% of the final mixture or 60% of the total volume infused.

Crystalline amino acid solutions are the main source of nitrogen in parenteral mixtures. They contain essential and nonessential amino acids at various concentrations, with solutions containing 8.5% amino acids used most commonly. Again, as with concentrated dextrose solutions, these products are high in osmolarity, approximately 800 mOsm/L. Because of the lability of the essential amino acid tryptophan, one should store these solutions at room temperature and protect them from light. Amino acid solutions are available with added electrolytes in the free-base rather than chloride form, reducing the risk of hyperchloremia. Final amino acid concentrations of most standard admixtures should not exceed 4.5%. One must mix amino acid solutions first with the dextrose solution before adding them to the lipid solution. The high pH of these solutions breaks the emulsion if added directly to the lipid solution.

Lipid emulsions often are used to increase the energy density and nonprotein nitrogen calories of a solution and supply the essential fatty acids linoleate and linolenate. Though high in caloric density at 9 kcal/g, these solutions have the added advantage of being isotonic. All are composed of soybean oil or a combination of soybean and safflower oil, with egg yolk phospholipids and glycerin acting as the emulsifying agents. One can piggyback lipid emulsions into the main line below the filter or add them into premixed dextrose–amino acid solutions to provide an all-in-one mixture. Lipid emulsions are the most expensive component of the admixture. Lipid emulsions should not constitute more than 50% of the total calories to prevent the suppression of the immune response reported in vitro and in vivo.[166–168] Table 5-21 lists products available for parenteral admixtures. 262

TABLE 5-21 Products for Parenteral Alimentation

A. DEXTROSE SOLUTION CONCENTRATE (g/dl)	OSMOLARITY (mOsm/L)	CALORIES (kcal/L)	MAINTENANCE REQUIREMENT (L)[a]
2.5	126	85	71
5.0	253	170	35
10.0	505	340	18
20.0	1010	680	9
50.0	2520	1700	4

B. LIPID EMULSIONS

PRODUCT	CONCENTRATION (g/dl)	OSMOLARITY (mOsm/L)	CALORIES (kcal/L)
Intralipid[b]	10 (20)	280 (330)	1100 (2000)
Liposyn[c]	10 (20)	276 (340)	1100 (2000)

C. CRYSTALLINE AMINO ACIDS

PRODUCT (WITHOUT ELECTROLYTES)	CONCENTRATION (g/dl)	TOTAL NITROGEN	OSMOLARITY (mOsm/L)
Aminosyn[d]	8.5 (10.0)	13.4 (15.7)	850 (1000)
Travasol[e]	8.5 (10.0)	14.3 (16.8)	860 (1060)

D. SUPPLEMENTS

MULTIVITAMIN CONCENTRATE (M.V.C. 9 + 3)[f]				TRACE ELEMENTS (M.T.E. 5 [1-mlVIAL])[g]	
Ascorbic acid	100.0 mg	Niacin	40 mg	Zinc	5.0 mg
Vitamin A	3300.0 IU	Pantothenic acid	15 mg	Copper	1.0 mg
Vitamin D	200.0 IU	Vitamin E	101 IU	Manganese	0.5 mg
Thiamine (B_1)	3.0 mg	Biotin	60 μg	Chromium	10.0 g
Riboflavin (B_2)	3.6 mg	Folic acid	400 μg	Selenium	20.0 g
Pyridoxine (B_6)	4.0 mg	Vitamin B_{12}	5 μg		

a Maintenance for 50-kg foal is 120 kcal/kg per day or 6000 kcal.

5.6.2.11.2

Guidelines for Delivery

As with enteral feeding, one must correct all fluid, electrolyte, and acid-base abnormalities before initiating any feeding. Energy goals for parenteral support are similar to those for enteral support. Table 5-22 lists some admixtures that have been used in partial and total parenteral support.

A central venous line (i.e., jugular) is preferred to using a peripheral vein because of the large volume of fluid required and the risk of thrombogenesis when hypertonic solutions are infused into small vessels. For mature horses, 16-gauge Silastic or polyurethane catheters 5 to 7 inches long have been recommended.[164,169] One should place catheters according to the guidelines of the manufacturer using strict aseptic techniques.[169] Once one establishes a line, dedicating this line for parenteral feeding only is best to reduce the risk of contamination. Dedication may not always be possible or practical. If a single line is necessary, aseptic technique is essential.[170] One should not use stopcocks so as to maintain a closed system. At no time should one draw blood through this line.

Gradual introduction of parenteral feeding solutions reduces the risk of complications. For adult horses, one should compute the desired goal, including injury factors, and prepare a mixture to infuse over the first 24 hours that will provide roughly half of the caloric needs of the patient. One can formulate most starter solutions using dextrose and amino acids. One can add lipids as an energy source when one cannot resolve hyperglycemia by decreases in rate alone. One adjusts the composition and rate of flow according to metabolic tolerance and nutrient need.

5.6.2.11.3

Complications of Parenteral Feeding

One may pattern monitoring procedures for the adult equine after those suggested for foals (Table 5-23). When lipid emulsions are included in the parenteral solution, one should check blood samples for evidence of lipemia. Serum triglycerides should be less than 150 mg/dl. If lipemia occurs, decreasing the rate of administration or administering heparin or insulin should improve clearance.

Hyperglycemia, glucosuria, and rebound hypoglycemia can occur. The insulin resistance and reduced 263
glucose use during sepsis, shock, and major trauma lead to the hyperglycemic state. Careful monitoring of 264
blood and urinary glucose concentrations and gradual weaning onto solutions over 24 to 36 hours can reduce the likelihood of occurrence. One should monitor serum and urine glucose concentrations at least 2 to 3 times per day and more often during introduction. When glucose concentrations greater than 200 mg/dl are present, one should decrease the flow rate until tolerance is achieved. Substituting some of the carbohydrate calories for fat calories also reduces the glucose load.

TABLE 5-22 Suggested Admixtures for Parenteral Nutrition of Horses

Data from Hansen TO: Nutritional support: parenteral feeding. In Koterba AM, Drummond WH, Kosch PC, editors: *Equine clinical neonatology,* Philadelphia, 1990, Lea & Febiger; Spurlock SL: *A practical approach to parenteral nutrition in the equine patient,* Deerfield, Ill, Baxter Healthcare, 1990; and Hansen TO, White NA, Kemp DT: Total parenteral nutrition in four healthy adult horses, *Am J Vet Res* 49:122, 1988.

1 g dextrose = 3.4 kcal; 1000 ml dextrose = 1700 kcal (500 g) 1 g amino acids = 4 kcal; 1000 ml 8.5% solution = 340 kcal (85 g) 1 g lipid emulsion = 11 kcal; 1000 ml 10% solution = 1100 kcal (100 g)

* *CHO,* Carbohydrates.

Rebound hypoglycemia occurs with a sudden cessation of glucose delivery without provision of an alternative source of enteral carbohydrate calories. One can prevent rebound hypoglycemia by slowly decreasing the rate of infusion by half for 12 hours while gradually increasing enteral support. One should take further decreases in accordance with patient response.

Azotemia and hyperammonemia are complications of protein metabolism that have been reported. Providing insufficient calories from nonprotein sources results in the amino acids being used for energy instead of protein synthesis. Assessing serum ammonia and blood urea nitrogen concentrations during total parenteral nutrition administration is recommended. The most common electrolyte abnormalities are

hypokalemia and hypomagnesemia.[164,171] Increased tissue synthesis increases the requirement for potassium and magnesium. Moreover, potassium also may be lost during glucose-induced osmotic diuresis.[172] One should follow supplementation with laboratory assessment to monitor status.

One of the common and serious mechanical complications that can develop in parenteral delivery is venous thrombosis.[169,173] One can reduce the risk of venous thrombosis by selecting catheters made of Silastic elastomers or the newer polyurethanes. Studies in human and veterinary medicine have documented the low thrombogenicity of these materials compared with polyethylene, polyvinyl chloride, or Teflon.[164,169,174]

5.6.2.11.4 Transition to Enteral Feeding

The transition to liquid or solid diets from parenteral delivery should gradual over 3 to 5 days to allow for
the stimulation of gut activity and digestive enzyme synthesis. Maintaining both systems of feeding for a 264
short period also guards against short-term nutrient deprivation should inappetence return. A survey of 265
transitional feeding practices in the human hospital setting indicated that parenteral nutrition most often was terminated when 50% to 75% of the calories were met orally.[175] This would appear reasonable for horses. The speed of progress is based largely on gastrointestinal tolerance. No transition protocols are established for horses. One may take a conservative approach by feeding 25% of caloric needs by the oral route in small, frequent meals and reducing the volume infused isocalorically at the expense of lipid. One can advance the transition daily in 25% increments as tolerance permits. Discontinuation of parenteral feeding when the horse has received 75% of its caloric needs enterally for at least 36 to 48 hours with no complications is probably reasonable.

TABLE 5-23 Monitoring Procedures for Parenteral Alimentation

OBSERVATION[*]	INITIAL MONITORING FREQUENCY	MONITORING AFTER STABILIZATION
Vital signs	q4h	q8h
Catheter, vein inspection	q8h	q8h

5.7 Nutritional Management of the Premature or Compromised Foal

Approximately half of the length and two thirds of fetal weight gain occur during the last 3 to 4 months of gestation.[28] The high metabolic rate and nutrient needs of the foal present many nutritional challenges. A premature or dysmature foal has been denied the benefit of intrauterine growth and nutrient transfer and therefore may not have the nutrient reserves of a full-term foal. In many cases, providing nutritional support can mean the difference between a positive and negative outcome.

5.7.1 NUTRIENT REQUIREMENTS

The nutritional requirements of the sick foal have not been defined, and lack of relevant data in the human pediatric literature provides little guidance. The issue of whether sick foals should or can be fed to support growth has not been resolved, though most would agree obtaining growth is a preferred goal. For healthy, preterm infants, growth rates similar to those of full-term infants during the last 30 days in utero are desired. In foals, growth rates comparable to those of equine fetuses during the last 30 days of gestation (0.5 to 0.7 kg/day) occur at 90 to 100 kcal DE per kilogram in healthy foals[28,176] and may be a reasonable starting point for

premature and sick foals. Additional increases may be needed for metabolic alterations induced by disease or trauma, but whether they are analogous to the injury factors applied to adults is not known. Caloric intakes between 120 and 160 kcal DE per kilogram have been reported to provide acceptable responses with minimal complications.[177]

Though only limited data were available, weight gains of foals receiving parenteral nutrition were found to be correlated negatively with the NPCal/N ratio, reemphasizing the need for a balance between protein and energy to achieve proper utilization of nutrients.[175] Nursing foals consume 6 to 7 g protein per kilogram of body mass during the first 2 weeks of life.[42] The NPCal/N ratio in mare's milk is approximately 105:1, slightly below that of several milk substitutes and much lower than that of most parenteral admixtures suggested for foals.[164,171] The current recommendations for the foal are higher than those for the human infant, especially considering their preciosity and rapid growth. Ratios less than 176:1,[164,176] and perhaps closer to the ratio of mare's milk, may be of greater benefit, but more studies are needed.

Between birth and 4 months of age, estimates of calcium and phosphorus accretion in foals appear to be 10 g/kg and 5 g/kg of gain, respectively.[2,50] If these values are taken as minimal and allowing for lower dietary availabilities from inorganic sources and reported endogenous losses, calcium and phosphorus requirements for neonates are at least 20 to 25 g/day and 10 to 16 g/day, respectively.[2] For foals gaining as little as 0.8 kg/day, extrapolation of these data suggests at least 18 g of calcium and 9 g of phosphorus are needed for neonates.

Again, one must estimate vitamin and trace mineral needs from the paucity of data in healthy foals and the nutrient content of mare's milk. Assuming that the foal would consume approximately 14 qt of milk per day 265
during the first week, the vitamin and trace mineral intake in Table 5-24 seems to be a reasonable starting place. 266

TABLE 5-24 Estimated Daily Trace Mineral and Vitamin Intake From Mare's Milk During First Week of Life

NUTRIENT		AMOUNT
Trace minerals	Iron	10.0 mg
	Copper	7.0 mg
	Manganese	17.0 mg
	Zinc	40.0 mg
	Selenium	0.09 mg
Vitamins	Thiamine	4.2 mg
	Riboflavin	4.9 mg
	Pyridoxine	5.4 mg
	Niacin	12.3 mg
	Pantothenate	117.5 mg
	Folic acid	1082.0 μg
	Biotin	116.0 μg
	Choline	964.0 mg
	B_{12}	40.9 μg
	Myo-inositol	984.0 μmg

5.7.2

ENTERAL SUPPORT

Generally accepted practice is to attempt enteral nutrition whenever possible. Lactase activity is present in the fetal small intestine during the last trimester, reaching its peak at 2 days post partum,[69] suggesting that a premature foal may have digestive capability. Intermittent enteral feeding most closely mimics the natural state, stimulating gastrointestinal enzyme and hormone activity and increasing small intestinal villous growth. Fewer complications are associated with enteral feeding (though some do exist), less monitoring is required, and enteral feeding is less expensive than providing nutrients parenterally.

5.7.2.1

Formulae

One should use mare's milk whenever possible. Because the goal is ultimately to return the foal to the mare, hand milking the mare provides food for the foal and helps to maintain lactation. Mare's milk has no discernible odor and has the appearance of 2% low-fat cow's milk. One should not use any milk that appears abnormal. One should strain the milk through a gauze sponge to remove hair, dirt, and other debris before storing and should keep it refrigerated.

Unfortunately, not all mares tolerate hand milking, and some stop lactating despite continual and frequent evacuation of the udder. Supplementation with other substitutes is usually necessary. Because of increased

endogenous losses, incomplete absorption, and the lower digestibility of nutrient sources compared with what nature provides, pediatric researchers have found that the concentration of most nutrients in infant formulae must be higher, especially those for the preterm infant.[178] This situation may well be applicable to compromised foals. The milk substitutes designed for the healthy orphan traditionally have been used for sick foals, but their efficacy has been highly variable, and many are too nutrient-dilute for sick foals when smaller feeding volumes are indicated.[179] A new nutrient-dense, equine neonatal formula is now available for such foals (NutriFoal, KenVet). This formula is similar in caloric distribution to goat's milk but has added protein to meet the needs of the young foal. (For the nutrient content, see Table 5-13). The casein-to-whey ratio and addition of the amino acid arginine results in an amino acid pattern similar to that of mare's milk protein. Minerals, vitamins, carnitine, and taurine have been added at levels to maintain nutrient balance.

5.7.2.2 Method of Delivery

For bottle feeding, most foals prefer the soft lamb nipples over the large, wide-bore calf nipples. When nasogastric delivery is needed, polypropylene enteral nutrition bags or flexible 1-L containers are ideal for the smaller volumes needed for foals. An attached in-line drip chamber and clamp permits control of the formula flow.

Stallion catheters (¼-inch outer diameter) and foal stomach tubes(⅜-inch outer diameter) of polyvinyl chloride or silicone have been used traditionally. Small-diameter (12F) polyurethane enteral feeding tubes adapt well for use in foals (Flexiflo Nasoenteric Feeding Tube #475, Ross Products Division, Abbott Laboratories, Columbus, Ohio). A stylet provides enough rigidity to prevent kinking during placement. A U tube placed at the nares helps to keep the tube in place. Foals have been fed for as long as 14 days with no signs of discomfort, irritation, or ulceration.[180] One should cap the Y connector with side port when not in use. One secures the tube by tape or by butterfly suture to the muzzle of the foal.

5.7.2.3 Rate of Delivery

For most foals in intensive care, intermittent or continuous drip results in the fewest complications. Foals that become colicky or bloated following even the smallest bolus feedings usually can tolerate slower, continuous infusions well. As the physical condition and gastrointestinal tolerance of the foal improve, one may attempt larger bolus feedings. Advancement to bolus feedings should be gradual by keeping the same per-feeding volume and slowly decreasing the time over which it is given. For example, if one feeds a foal intermittently
by infusing 1350 ml over 3 hours every 4 hours, one should advance the feeding to 1350 ml over 2 hours 266
every 4 hours. If the foal maintains tolerance for 24 to 48 hours, one should advance until attaining the desired 267
bolus schedule.

5.7.2.4 Guidelines for Enteral Feeding of the Compromised Foal

The following are guidelines for enteral feeding of compromised foals:

1. Correct the hydration, electrolyte, and acid-base status of the foal before initiating feeding.
2. Obtain the weight of the foal and estimate its energy needs. Start at 100 kcal/kg, with a goal of 120 to 150 kcal/kg.
3. Estimate the protein needs. Maintain an appropriate NPCal/N or Cal/N ratio.

4. Select the formula to be used and calculate the volume needed.
5. Place the indwelling nasogastric tube using the approved clinic procedure and following the guidelines of the manufacturer. If the tube becomes dislodged, do not attempt to reinsert the stylet into the dwelling tube. Remove the tube, reinsert the stylet, and replace the tube. As with adults, one must verify the proper placement of the tube, preferably by radiography or endoscopy.
6. Foals should be standing (if able) or in sternal recumbency during feeding. This helps to prevent gastric reflux and reduces the risk of aspiration pneumonia, a common and frequently fatal complication of sick foals.
7. The sicker the foal, the more intolerant it generally will be of feedings. In some cases, intolerance caused by early aggressive feeding is difficult to reverse. The conservative approach is best. Begin with half the desired volume and increase gradually after at least 24 hours, using tolerance as a guide. Intermittent or continuous feeding is recommended over bolus delivery. Start at 100 ml/hr and increase to 300 ml/hr as quickly as tolerance allows.
8. Check for gastric residuals before feeding. Gastric emptying is reduced in sepsis. If a volume greater than or equal to the designated feeding volume is present, do not feed and investigate possible causes.
9. Flush the tube before feeding to verify patency and placement. If resistance to flushing occurs, formula exits from the nostril(s) of the foal, or the foal is in distress, do not feed. Flush the tube after feeding to rinse out formula and prevent clogging.
10. After rinsing the tube, cap the feeding port to prevent air from entering the tube and formula from siphoning out.
11. Colic, constipation, and diarrhea are common problems that are not always diet related. Though one should discontinue feeding until the cause has been identified, prolonged gut rest (greater than 24 to 36 hours) may further compromise the foal. One should reverse parenteral support for those foals for which all attempts to feed enterally have been unsuccessful.
12. If the goal is to put the foal back on the mare, encourage suckling from the mare or a bottle to develop the suckle reflex as soon as the foal is able. If the foal is to be reared by hand, teach the foal to drink from a shallow container and raise the foal as suggested for an orphan.
13. Caution owners not to overfeed the foal in an effort to catch up with others of similar age. Premature and sick foals need time to continue recovery, even after release. Overfeeding will not be rewarding. One should feed foals according to their current age and weight rather than according to the weight of age-matched normal foals.

5.7.3 PARENTERAL SUPPORT

Table 5-22 summarizes suggested parenteral solutions for use in foals.[171,181] Initial caloric goals vary from 55 to 100 kcal/kg and are dictated primarily by the clinical status of the foal; for example, the sicker the foal, the lower the initial goal probably should be to minimize complications. Protein goals in current protocols range from 2 to 3 g/kg body mass. Fat intake from mare's milk early in lactation ranges from 5 to 6 g/kg body mass, slightly higher than the 2 to 4 mg/kg of most parenteral solutions. Other supplements added to the solution include

vitamins, trace minerals, and potassium chloride for foals not receiving enteral feedings. In human beings, potassium and protein coexist in body tissues in a constant ratio. Catabolic patients can lose as much as 3 mEq potassium in the urine for each gram of protein that is lost. Without adequate potassium, protein synthesis is depressed.[182] Osmotic diuresis that occurs during hyperglycemia and diuretic-induced diuresis also can increase potassium lost through urine.[162,183] To counter these losses, 40 to 60 mEq potassium has been added per liter of parenteral solution for foals. Calcium and phosphorus concentrations of admixtures fed to foals is not adequate to meet the needs of growing foals. One safely can add calcium gluconate (25 to 50 mEq/L) and potassium phosphate (5 to 15 mEq/L) to provide part of the needs until enteral feeding is possible.[183] Additional calcium supplementation to the admixture runs the risk of mineral precipitation.

One should take care to begin infusions slowly and increase it gradually. One may not achieve the goal infusion rate for 12 to 24 hours, depending on the foal. One can monitor patient tolerance to the parenteral mixture by using the schedule in Table 5-23.[184] One should wean foals from parenteral support along with the introduction 267
of enteral feeding. Rebound hypoglycemia should not be a problem as long as sufficient calories are provided 268
enterally. Parenteral support is best withdrawn over 2 to 3 days and followed with 1 to 2 L of 5% dextrose to aid in reestablishing glucose control mechanisms.[183]

One should base advances in volume or the inclusion of lipid emulsions on metabolic tolerance. As in human infants, lipid emulsions are not recommended for foals with hyperbilirubinemia, for this may further compromise bilirubin transport.

6 CHAPTER 6 CRITICAL CARE

Joanne Hardy*

Equine intensive care units (ICUs) currently are integrating the following three critical components into many primary and referral hospitals: (1) the sickest patients; (2) highly technical and expensive equipment; and (3) staff with knowledge and experience to treat these patients. The goals of these units are to improve efficiency, improve efficacy, reduce cost, and ultimately improve patient outcomes.

One must base the decision to offer ICU services on the population needs, the consideration that emergency services should be offered also, and the economic environment of the hospital. Currently, few studies exist that describe the general case population, commonly performed procedures and treatments, and overall cost-benefit ratios of equine ICUs. One study described the overall case distribution of emergencies based on monthly admissions, the proportion of cases requiring surgery, and the most commonly performed treatments.[1] Because equine emergencies often are handled in ICUs, such information provides an initial database for understanding population dynamics. In that study, 20% of hospital admissions were received as after-hour emergencies. Approximately 60% of emergencies were for colic, of which approximately half required abdominal surgery. Other emergencies were distributed among the following categories: neonates (8%), orthopedics (7%), lacerations (5%), enteritis/colitis (4%), neurologic (4%), reproductive (4%), respiratory (4%), and others. In the miscellaneous category, the authors cited esophageal obstruction, ocular emergencies, rectal tears, hemorrhage, and undefined sickness. Although this case distribution probably reflects accurately the overall equine emergency caseload, reviewing the anticipated distribution of cases within a given area and the monthly distribution of cases is important. Such reviews ensure appropriate allocation of staff and equipment, tailored to the needs of the population. For example, in the previously quoted study the peak colic case admission was in August. In contrast, the peak neonatal case admission was in April and May. In general, in the northern hemisphere, peak foal season extends from February through June, whereas in the southern hemisphere, peak foal season is from September to January. Such distribution requires different staffing needs. During foal season, the ICU may need technicians trained to use mechanical ventilators, blood gas analyzers, glucometers, capnographs, or other specialty equipment. Addition of temporary unskilled staff (foal sitters) to help with managing of neonates is useful. Regular review of equipment and training on new equipment for staff, technicians, and clinicians is essential for smooth running of an equine ICU.

Commonly and anticipated procedures performed in ICUs include monitoring, fluid administration, and pain control. Monitoring includes not only manual techniques but also use of equipment. Fluid administration encompasses routine administration not only of crystalloids but also of colloids, blood, and blood substitutes. Providing appropriate analgesia can vary widely depending on the origin of pain (musculoskeletal versus abdominal) and the possible side effects of different medications. All of these considerations need to be based on the specific needs of the equine patient.

6.1 Organization of an Equine Intensive Care Unit

The design of the ICU should accommodate the care of horses with abdominal disorders, care of neonates, and care of horses with infectious diseases that require isolation. In addition, the design should include one or two stalls for easy unloading of down horses with the structure able to withstand hoisting. A central office facilitates oversight of the unit, organization, and issuing of directives. Sufficient storage space should be available to protect equipment not in use. The isolation unit must be separate from the ICU and have strict protocol. Ideally, the adult ICU should be separate from the foaling and neonatal ICU stalls. All stalls should have the equipment necessary for hanging

fluids. Large foaling stalls should be available. These stalls can have mobile separators for foals receiving intensive care. Locations with a large neonatal caseload should include a separate room to manage foals separately from their dams, which enables provision for increased ambient temperature and increased cleanliness and facilitation of monitoring and management.

Strict disinfection and isolation protocols should be in place to prevent the spread of infectious disease and to avoid nosocomial infections. One should encourage hand washing and use of foot baths between patients, particularly when dealing with infectious diseases, even when these are not contagious. Hand rubbing with an alcohol-based solution is more effective than hand washing with an antiseptic, probably because it does not require rinsing and drying of hands. Adoption of this practice can reduce cross-contamination between patients significantly,[2] which is also important when dealing with exudative wounds in which resistant organisms can grow. Growth of an oxacillin-resistant staphylococcus species should alert one to the presence of a methicillin-resistant organism. Guidelines for the judicious use of antibiotic regimens are available for human ICUs, and some of these guidelines are applicable to equine ICUs. Guidelines include the initial empirical selection of effective antibiotic regimens based on history, disease process, possibility of nosocomial infection, and knowledge of specific isolates for the hospital. One should base appropriate dosing and administration protocols on selection of time-dependent or concentration-dependent antibiotics, immune status of the patient, and cost. Once one obtains culture results, one should deescalate or modify therapy. Other methods that have been proposed to minimize antibiotic resistance and superinfections include cycling of antibiotics and restricted use of potent, broad-spectrum therapies.[3]

Salmonella organisms also can be a cause of nosocomial infection in the equine hospital.[4] Salmonella shedding is greater in horses with colic, and the use of common equipment such as stomach tubes and pumps may promote transmission.[5–7] Careful attention to hospital design and disinfection practices can help minimize the risk of hospital outbreaks.[8,9]

A separate food preparation bay should be available for preparation of enteral feeding. Staff members should pay attention to cleanliness in this area and particularly should avoid washing of hands or contaminated material in the same sink used for food preparation.

Technicians and staff available in the unit should be trained in techniques performed in the ICU and in early recognition of problems relating to equipment malfunction and invasive and noninvasive monitoring techniques. Technicians also need to be trained to indentify changes in patient status. When complex cases require continuous monitoring, a veterinarian may need to be present continuously.

6.1.1 EQUIPMENT

One should tailor the equipment used in an equine ICU to the anticipated case population and the maximal level of care anticipated for that population. Purchasing a ventilator would be a poor economic decision if mechanical 274

275 ventilation rarely is performed. Alternatively, one should investigate the possibility of renting medical equipment from suppliers in the area for such intermittent needs. Box 6-1 lists some equipment to consider for the anticipated needs of a new equine ICU.

6.1.1.1 BOX 6-1 EQUIPMENT LIST FOR DIFFERENT LEVELS OF EQUINE INTENSIVE CARE UNITS

6.1.1.1.1 Basic

Fluid administration system

Electrocardiogram

Centrifuge

Refractometer

Glucose strips

Urinalysis strips

Ultrasound

Oxygen tank and regulator

6.1.1.1.2 Intermediate

Blood pressure monitor

Cytologic exam/Gram stain

Glucometer

Intravenous pump delivery system

Sling and hoist for down horses

6.1.1.1.3 Advanced

Blood gas/electrolyte analyzer

Pulse oximeter

Mechanical ventilator

Colloid osmometer

Capnograph

Syringe infusion pumps

The most commonly used procedure in equine ICU is catheter placement, followed by intravenous fluid replacement. The section on fluid therapy covers catheter placement. For adult horses, one usually hangs intravenous fluids in several 3- to 5-L bags and administers them by gravity flow. A pulley system facilitates

hanging of fluids bags in the volumes needed for administration in horses.* Commercially available coil sets enable intravenous fluid administration without restraint. The drip chamber should be large enough to be visible from outside the stall. Having a drip chamber that allows administration of other medication (piggy-backing) is convenient. Smaller horses, ponies, miniature horses, and foals benefit from a more precise means of monitoring the volume of fluid administered. One can provide such monitoring by using volumetric fluid chambers or fluid pumps; however, commercially available pumps can deliver only up to 999 ml/hr, which may be insufficient for standard-size horses. For rapid administration of large volumes of fluids—for example, to treat shock—peristaltic pumps are available that allow delivery of 20 to 40 L of fluid in the first hour. Because of the pulsatile nature of the fluid flow, this method of fluid administration causes more damage to the venous endothelium. For administration of constant rate infusions of small quantities of drugs, syringe pumps are also available.

Standard monitoring equipment for use in ICU includes an electrocardiogram and blood pressure monitor, an ultrasound unit, a centrifuge for hematocrit determination, a refractometer for determining total protein and urine specific gravity, and urine test strips for urinalysis. Other equipment to consider includes glucometer, urine centrifuge, microscope with 100× magnification, equipment for cytologic examination and Gram stains, and a blood gas and electrolyte monitoring unit. A colloid osmometer is useful for determining colloid oncotic pressure in sick animals. If the ICU plans to provide mechanical ventilation, useful monitoring units include capnographs and pulse oximeters. Monitoring equipment should have quality control measures that must be performed regularly to ensure accuracy. Staff members should follow appropriate sampling procedures for each piece of equipment.

Oxygen ports for supplementation through nasal insufflation or for mechanical ventilation should be available. When installing a new ICU, one should consider ports for oxygen, vacuum, and air. A remote gas source and a pipeline system allow delivery of oxygen. The ICU can use compressed gas cylinders, but these must be stored and handled appropriately to avoid injury. For each cylinder type, knowledge of the capacity of the cylinder and the flow rate enables calculation of the amount of time provided. The small more portable E cylinders, containing 655 L of oxygen when full, provide oxygen for 260 minutes when set at a flow rate of 5 L/min. Adult horses require flow rates of 10 to 15 L/min to increase the FIo_2 to approximately 40%. Larger G or H cylinders containing 5290 or 6910 L respectively, allow oxygen supplementation for longer periods. Tight-fitting masks have been used satisfactorily in foals to manage hypoventilation, but in adults, nasal insufflation using an oxygen cannula is tolerated better. In adults with severe respiratory distress that require a greater FIo_2, the clinician can perform a tracheostomy using a cuffed silicone cannula* for administration of oxygen. Oxygen should be humidified, and the FIo_2 should not exceed 50% for prolonged periods.

An emergency (crash) cart should be available in the ICU. Table 6-1 lists emergency drugs and dosages used in adult horses. One can place the list in the crash cart for easy reference. In addition, one should place emergency tracheostomy packs at key areas, such as near the stall of patients with possible respiratory distress, near recovery stalls, and in the patient receiving area.

Ultrasonography also has become an essential component of ICUs. Ultrasound can be used for identifying and monitoring effusions, intestinal distention and motility, identifying umbilical structures, imaging of joint effusions, diagnosing the presence and location of urine in the abdomen, monitoring pregnancy, and imaging of ocular structures, among other things. To enable imaging of different structures, 3.5- and 7.5-MHz transducers and rectal probes are the minimal needed for these purposes.

6.1.2 MONITORING

Patients in ICU require frequent monitoring. One should record all monitored parameters and preferably should display these on or near the patient's door for rapid review. More complete or extensive laboratory results can be stored in the patient's chart.

The remainder of this chapter describes aspects of fluid therapy in the adult and some important procedures performed in the ICU.

6.2 Fluid Therapy

Fluid administration for maintenance or replacement is one of the mainstays of equine critical care and should be 275
readily and easily available in any equine hospital. The availability of commercial materials and fluids for use in 276
large animals makes fluid administration easy and cost-effective in most situations. This section reviews materials available and principles to follow when planning fluid administration.

TABLE 6-1 Emergency Drug Chart for Adult Horses

DRUG	DOSE	DOSE PER 1000 lb	ROUTE*	COMMENT
Dobutamine (positive inotrope)	2–10 µg/kg/min (1 vial [250 mg] in 1000 ml = 250 µg/ml)	900–4500 µg/min	IV	Use diluted solutions within 24 hours. Is compatible with most IV fluids. Do not mix with alkaline solutions or calcium chloride/gluconate.
Doxapram (respiratory stimulant)	0.2 mg/kg	4.5 ml	IV or topical under tongue	Do not mix with alkaline drugs/fluids.
Epinephrine (for anaphylaxis or asystole)	0.01–0.02 mg/kg 0.1–0.5 mg/kg	4.5–9 ml	IV/IM/SQ Intratracheal	Do not give with bicarbonate, hypertonic saline, or aminophylline. Does not need to be diluted when given IV to adults.
Glycopyrrolate (for bronchodilation and bradycardia)	0.005–0.01 mg/kg	10–20 ml	IV/IM/SQ	Do not mix with alkaline drugs/fluids.
Lidocaine (treatment of ileus)	1.3 mg/kg loading slowly over 5 minutes 0.05 mg/kg/min infusion	Loading: 30 ml Infusion: 67 ml/hr	IV	Make sure product does not contain epinephrine.
Lidocaine (treatment of arrhythmias)	Bolus: 0.25–0.5 mg/kg (slowly) Infusion: 20–50 µg/kg/min	Bolus: 5–10 ml Infusion: 30–60 ml/hr	IV	Make sure product does not contain epinephrine.

* IV, Intravenous(ly); IM, intramuscularly; SQ, subcutaneously.

6.2.1 MATERIALS FOR FLUID ADMINISTRATION

6.2.1.1 Intravenous Catheters

Intravenous catheters are available in varying materials, construction, length, and diameter. In choosing a catheter, one should consider desired fluid rate, fluid viscosity, the length of time the catheter will remain in the vein, the severity of the systemic illness, and the size of the animal (Table 6-2). The rate of fluid flow is proportional to the diameter of the catheter and inversely proportional to the length of the catheter and the

viscosity of the fluid. Standard adult horse catheter sizes are usually 14 gauge in diameter and 5.25 inches in length. For more rapid administration rates (such as for shock), one should use a 12- or 10-gauge catheter. Plasma and blood products, because of their increased viscosity, also flow slower, so if the horse requires volume replacement, one can combine administration of these fluids with a balanced electrolyte solution. One should change Teflon catheters every 3 days, whereas polyurethane catheters can remain in the vein for up to 2 weeks. Horses that are very ill (bacteremic, septicemic, endotoxic) are more likely to encounter catheter problems and benefit from polyurethane or silicone catheters.

276

277

One also must consider the catheter construction (Table 6-3). Through-the-needle catheters are most common for standard-size adult horses. An over-the-wire catheter is best used in foals and miniature horses or when catheterizing the lateral thoracic vein. Short and long extension sets are available, as well as small and large bore diameters. Using an extension that screws into the hub of the catheter is best, to avoid dislodgement. In horses with low central venous pressures, disconnection of the line can result in significant aspiration of air and cardiovascular collapse. Double extensions are also available for when the horse requires administration of other medication with the fluids.

TABLE 6-2 List of Available Catheter Materials

MATERIAL	EXAMPLE	COMMENT
Polypropylene	PE tubing, Medicut	Highly thrombogenic; not recommended
Teflon	Angiocath	Less thrombogenic
Polyurethane	Mila	Much less thrombogenic
Silastic	Centrasil	Least thrombogenic

TABLE 6-3 List of Commercially Available Catheter Constructions

TYPE	DESCRIPTION	ADVANTAGE	DISADVANTAGE
Butterfly	Needle attached to tubing	Ease of use	Laceration of vessel; vessel puncture and extravascular administration
Over-the-needle	Stylet inside catheter for venipuncture	Available in large diameter	Limited length of catheter
		Ease of insertion	Not flexible; break at catheter and hub junction
Through-the-needle	Short needle is inserted; catheter is threaded through needle	All lengths available Flexible Peel-away needle	Technically more difficult to insert
Over the wire	Needle serves as guide to insert wire, which serves as guide for catheter	Flexible; long catheters available; ensures proper catheter placement	More technical expertise required to place catheter; expensive

6.2.1.2 Catheter Maintenance

In adult horses, one usually does not cover a catheter with a bandage, so that one can identify any problem quickly. One may need to apply bandages in foals if they are tampering with the catheter. A triple antibiotic ointment may be applied at the insertion site on the skin to decrease infection. One should flush catheters with heparinized saline (10 IU/ml) 4 times a day if they are not used for fluid administration. When administering a medication, one should wipe the injection cap with alcohol before inserting the needle and should change the injection cap daily. One should culture all infected catheters for identification of the causative organism and for possible nosocomial infection.

6.2.1.3 Coil Sets and Administration Sets

Coil sets are used for in-stall fluid administration and are essential because they allow the horse to move around, lie down, and eat without restraint. An overhead pulley system with a rotating hook prevents fluid lines from getting tangled.

Administration sets are used for short-term fluid or drug administration and are available at 10 drops/ml and 60 drops/ml. When using a calibrated fluid pump, one should take care to use the appropriate set calibrated for the brand of pump. One then can use long coiled extension sets to connect fluids to the horse. Foal coil sets are also available that deliver 15 drops/ml.

Special foal fluid administration sets are available as pressurized bags that allow delivery of fluids at 250 ml/hr. These bags can be placed in a special harness on the back of the foal, thereby avoiding entanglement with the mare.

6.2.1.4 Pump Delivery

Calibrated pumps are available that allow delivery at various rates. These pumps have alarms that signal air in the line, an empty fluid bag, or catheter problems. The maximal fluid rate these pumps can deliver is 999 ml/hr, which is not enough for an adult horse. The pumps are useful for recumbent foals or for combined drug infusions. For large volume fluid delivery, peristaltic pumps are available that can deliver up to 40 L/hr. One must supervise these pumps constantly when in use because they continue to run even if fluids run out. One should use large-bore catheters to avoid trauma from the jet effect on the endothelium of the vein.

6.2.1.5 Sites for Intravenous Catheterization

Common sites for insertion of intravenous catheters in horses include the jugular, lateral thoracic, cephalic, and saphenous veins. The lateral thoracic vein makes an acute angle as it enters the chest at the fifth intercostal space; therefore an over-the-wire catheter is best to use when catheterizing this vein. Catheters placed in any location other than the jugular require more frequent flushings (every 4 hours), because they tend to clot more easily. Leg catheters usually are bandaged because they are more prone to dislodgment than jugular catheters.

6.2.1.6 Oral Feeding Tubes

Oral fluid administration offers a good alternative to intravenous fluid therapy in animals that require 277
maintenance fluids because of inability to swallow or in horses with impaction colic. One also can administer 278

complete or partial enteral nutrition for foals and adults. Commercially available feeding tubes for foals, weanlings, and adults* enable fluid or liquid diet supplementation while allowing the horse to continue to nurse or eat (Figure 6-1).

Figure 6-1 An adult horse with a nasogastric feeding tube in place for administration of fluids or enteral feeding solutions.

* Mila International, Florence, Kentucky, www.milaint.com

6.2.2

DESIGNING A FLUID THERAPY REGIMEN

Administration of fluid therapy can be for maintenance or replacement. Horses usually receive maintenance regimens orally, and oral electrolyte formulations are available for this purpose. Intravenous maintenance fluids

are lower in sodium and higher in calcium, potassium, and even magnesium than replacement fluids. Replacement regimens replace fluids lost through dehydration and ongoing losses.

When designing a fluid therapy regimen, one must answer three questions:

- What volume of fluid must be given?
- What type of fluid will be given?
- What will be the rate of administration?

The volume of fluids to give equals the maintenance requirements plus the correction for dehydration and for ongoing losses.

6.2.2.1 Maintenance

In the adult horse, maintenance fluid requirements have been estimated at 60 ml/kg/day. This figure probably overestimates the actual needs of a resting, fasted animal but appears to be safe in most situations. In horses with renal failure, where elimination of excess fluids is problematic, monitoring of body weight and central venous pressures is indicated. If one notes weight gain, edema, or increased central venous pressure, one should decrease the fluid administration rate.

6.2.2.2 Dehydration

Evaluation of dehydration is at best a subjective estimate, and the clinician must understand that this estimate will need to be adjusted based on monitoring parameters. Table 6-4 lists useful parameters for evaluating acute, extracellular dehydration.

Once one obtains an estimate of dehydration, one can calculate the amount of fluids to be given as follows:

$$\text{Correction of dehydration} = \text{Estimate of dehydration (\%)} \times \text{body mass (kg)}$$

6.2.2.3 Ongoing Losses

Sometimes one can measure and record ongoing losses—for example, for nasogastric reflux—but most commonly one must estimate ongoing losses. One monitors the patient to determine whether the calculated fluid volume is meeting the ongoing losses. One should monitor patients given fluids intravenously at least twice a day, including heart rate and measurement of packed cell volume and total protein, but one should monitor more frequently (every 2, 4, or 6 hours) depending on the severity of cardiovascular compromise. One should also monitor creatinine concentration once daily when initially elevated to ensure adequate return to normal. Additional means of monitoring adequate fluid delivery may include measurement of central venous pressure, arterial blood pressure, and urine output.

6.2.2.4 Type of Fluid

The type of fluid to give depends on evaluation of the chemistry profile and disease state. The first step is to decide on the baseline fluid (saline or balanced electrolyte solution), and the second step is to decide on which

additives to add to the baseline fluid, depending on specific deficits or excesses, such as hypo- or hypernatremia, hypo- or hyperkalemia, hypo- or hypercalcemia, hypoglycemia, or acid-base disorders.

Two categories of fluids commonly are used for fluid replacement: 0.09% saline and balanced electrolyte solutions (BESs). Table 6-5 lists the composition of various commercially available fluids. In general, one chooses BESs when serum electrolytes are close to normal. All BESs contain some potassium. Saline is higher in sodium and much higher in chloride than serum concentrations and is used when sodium is lower than 125 mEq/L. Saline also is used in disease processes associated with high potassium such as hyperkalemic periodic paralysis or with renal failure, in which a potassium-free solution is preferable. In cases of long-term fluid maintenance therapy (greater than 4 to 5 days), if the oral route is not available, one should consider half-strength basic fluids to which potassium and calcium are added. Long-term fluid therapy with routine BESs results in hypernatremia, hypokalemia, hypomagnesemia, and hypocalcemia. 278 279

TABLE 6-4 Parameters Used for Estimation of Dehydration in the Horse

% DEHYDRATION	HEART RATE (BEATS PER MINUTE)	CRT (SECONDS)*	PCV/TP (%/g/L)*	CREATININE (mg/dl)
6	40–60	2	40/7	1.5–2
8	61–80	3	45/7.5	2–3
10	81–100	4	50/8	3–4
12	>100	>4	>50/>8	>4

* CRT, Capillary refill time; PCV, packed cell volume; TP, total protein.

In horses, routine fluid replacement includes calcium and potassium supplementation, in particular when the horse receives no oral intake because of gastrointestinal disease. Both electrolytes are important for smooth muscle function and vascular tone. Recently, magnesium supplementation also has received interest, particularly with fasting and ileus.[10,11]

Horses with metabolic acidosis also may require bicarbonate supplementation. Because the most common cause of nonrespiratory acidosis is lactic acidemia resulting from poor perfusion, providing fluid replacement should be the first and principal means of correcting this problem. Rules of thumb for bicarbonate supplementation in *acute* metabolic acidosis are as follows:

- Normal respiratory function: If the horse is unable to exhale the generated CO_2 because of a respiratory problem, the acidosis will worsen.
- pH <7.2: In acute acidosis associated with dehydration, fluid replacement results in restoration of urine output, and renal compensation follows and usually is complete if the pH is greater that 7.2.
- Administration of half of the calculated amount rapidly, followed by the rest over 12 to 24 hours.
- Intravenously administered bicarbonate and calcium-containing solutions are incompatible.

In chronic metabolic acidosis, particularly with ongoing losses of bicarbonate (e.g., diarrhea), the horse usually requires the full calculated amount, partly because the bicarbonate loss is distributed over all fluid

compartments, not just the extracellular fluid. Orally administered bicarbonate is a good means of dealing with ongoing losses in horses with diarrhea.

TABLE 6-5 Crystalloid Solutions Available for Fluid Therapy

PRODUCT	APPROXIMATE pH	mOsm/L	Na (mEq/L)	K (mEq/L)	Ca (mEq/L)	Mg (mEq/L)	Cl (mEq/L)	BUFFER (mEq/L)
Lactated Ringers	6.5	273	130	4	3	—	109	Lactate 28

5% $NaHCO_3$	8	1190	595	—	—	—	595	—
8.4% $NaHCO_3$	—	2000	1000	—	—	—	1000	—
1.3% $NaHCO_3$ (must be mixed)	—	308	154	—	—	—	1541	—

Bicarbonate can be given orally as a powder, where 279

280

$$1\ \mathrm{g}\ NaHCO_3 = 12\ \mathrm{mEq\ of}\ HCO_3$$

6.2.2.5 Rate of Administration

In severe shock, one should give a shock dose of fluids in the first hour (60 to 80 ml/kg), which can be done only with pressurized bags or a pump.

In other situations, one calculates the rate of administration based on 24-hour requirements and estimates as a volume per hour. Keeping tally of the fluids given is important to ensure that the correct amount is given.

6.2.2.6 Orally Administered Fluids

One can provide orally administered fluid therapy using the following fluid composition for every 21 L of water:

$NaCl$	10 g
$NaHCO_3$	15 g
KCl	75 g
K_2HPO_4	60 g

One should administer calcium separately because it causes precipitation of the solution. This electrolyte solution meets daily needs for an adult horse and can be given by a small, preplaced nasogastric feeding tube or by intermittent intubation.

6.2.3 FLUIDS USED TO EXPAND CIRCULATING BLOOD VOLUME

6.2.3.1 Isotonic Crystalloids

Intravenous administration of isotonic crystalloids immediately reconstitutes circulating volume. However, because the fluids are crystalloids, they distribute to the entire extracellular compartment within a matter of minutes. Because the extracellular fluid compartment is 3 times the volume of blood, one must administer 3 times as much isotonic crystalloid to gain the desired amount of volume expansions.

The dose is 60 to 90 ml/kg/hr, and the fluid types usually are BESs such as lactated Ringer's solution.

6.2.3.2 Hypertonic Crystalloids (7.2% NaCl)

Hypertonic crystalloids are approximately 8 times the tonicity of plasma and extracellular fluid; their immediate effect is to expand the vascular volume by redistribution of fluid from the interstitial and intracellular spaces. However, this effect is short lived. As the electrolytes redistribute across the extracellular fluid, fluids shift again and the patient becomes hypovolemic again. Because the principal effect is fluid redistribution, a total body deficit still exists that must be replaced. The duration of effect of hypertonic solutions is directly proportional to the distribution constant, which is the indexed cardiac output.

The dose is 4 ml/kg, administered as rapidly as possible, and the fluid is 5% or 7% saline.

Because of its short duration of effect, one must follow hypertonic saline administration with isotonic volume replacement.

6.2.3.3

Colloids

Colloids are fluids that contain a molecule that can exert oncotic pressure. These molecules do redistribute to the extracellular fluid but at a much slower rate than crystalloids, so that the duration of effect is prolonged compared with crystalloids. Table 6-6 describes the different colloids available.

Natural colloids (plasma or albumin) have the disadvantage that they are more antigenic and can cause allergic reactions. Synthetic colloids have a much lower antigenicity, but they can cause bleeding disorders by their tendency to coat platelets or by causing a decrease in coagulation factor. In the horse, Dextran 40 can cause anaphylactoid reactions. Hetastarch administration can cause a decrease in coagulation factors and prolong clotting times, particularly at high doses (20 ml/kg).[12]

The dose is 10 ml/kg of 6% solutions.

Synthetic colloids do not register on a refractometer. One can evaluate oncotic pressure accurately only by using a colloid osmometer. If one is not available, one must use clinical evaluation (presence of edema and poor circulatory volume and pressure).

6.2.3.4

Blood Substitutes

Blood substitutes are hemoglobin solutions. Currently, only one commercial hemoglobin solution (oxyglobin, which is made from bovine hemoglobin) is available. The major advantage of oxyglobin is that it does not depend on 2,3-diphosphoglycerate for oxygen-carrying capacity, such that it can be stored and is immediately able to transport oxygen. The duration of effect is approximately 18 hours in horses, after which one must consider another dose or a blood transfusion.[13,14] Unfortunately, cost limits the usefulness of oxyglobin in horses.

6.2.3.5

Whole Blood

Whole blood is the ideal fluid for blood loss or platelet loss, providing it is fresh blood and has been cross-matched. One must remember that stored blood loses its oxygen-carrying capacity, and that it can take several hours to restore it after administration.

Ideally, the ICU should maintain blood donors that are free of antigenic determinants, particularly Aa and Qa and of isoantibodies. One can perform a major and minor cross-match to select an appropriate donor, providing complement is added to the test for hemolysin detection. Interpretation of the minor cross-match can be difficult if autoagglutination is present. If unavailable, one can use a non-Thoroughbred gelding. One can 280
collect a volume of 20 ml/kg safely every 3 weeks in adult horses[12] and can collect whole blood in sodium 281
citrate using sterile technique. Commercial blood collection kits are also available. Complications of blood transfusion include acute anaphylactic reactions, allergic reactions, hemolysis, fever, tachypnea, and hypocalcemia caused by citrate chelation.

TABLE 6-6 Characteristics of Colloids Solutions Available for Fluid Therapy

CHARACTERISTICS	5% ALBUMIN	25% ALBUMIN	OXYPOLYGELATIN	DEXTRAN 40	DEXTRAN 70	HETASTARCH
Molecular weight (d)

6.3 Monitoring Techniques in the Adult Equine ICU

6.3.1 ARTERIAL BLOOD PRESSURE

One can measure *arterial blood pressure* by direct catheterization of a peripheral artery or by indirect measurements that depend on a cuff placed over an artery and cuff inflation until blood flow is occluded. Measurement of arterial blood pressure is one of the indirect estimates of tissue perfusion, using the mean pressure as the driving pressure.

One can measure mean arterial blood pressure electronically by integrating the area under the pressure waveform and dividing this by the duration of the cardiac cycle.

Pulse pressure is the difference between systolic and diastolic pressure and is responsible for the palpable pulse. A bounding pulse pressure results from an increased systolic pressure or a depressed diastolic pressure.

Ultimately, the clinician is interested in oxygen delivery to tissues, which depends on adequate perfusion of tissues, which in turn depends on functional capillary density and blood flow in capillaries. In the clinical arena,

measurement of tissue perfusion or of tissue blood flow is impractical. Therefore clinicians use blood pressure as an estimate of adequate blood flow and tissue perfusion. The problems with this assumption are these:

- Tissue blood flow is regulated locally; an adequate systemic blood pressure may not reflect local blood flow if vasoconstriction, shunting, poor capillary recruitment, edema, or thromboembolism exist. An example is the central redistribution of blood flow in shock, with preferential shunting of abdominal organs.
- Blood flow depends on pressure differential. If vasoconstriction is generalized, blood pressure may be normal but flow may be poor.
- Blood flow through a vessel depends on the viscosity of the fluid (blood) and the radius of the vessel. At high viscosity, blood flow may be impaired. Severe vasoconstriction, although maintaining blood pressure, may impair flow.

6.3.2 DIRECT OR INVASIVE BLOOD PRESSURE MEASUREMENT

An over-the-needle catheter configuration is preferable for direct or invasive blood pressure measurement to avoid bleeding at the site of puncture. Preferably, one uses a small (20- or 22-gauge) catheter to minimize hematoma formation on catheter removal. The radial artery over-the-needle catheter* with a wire guide is suitable for arterial catheterization of peripheral vessels in the horse. As an alternative, one can use an over-the-wire catheter sheath† that uses a Seldinger technique for insertion. The catheter is connected to noncompliant 281
tubing filled with heparinized saline, which is linked to a pressure transducer. 282

Figure 6-2 An adult horse with an arterial catheter in the transverse facial artery for direct blood pressure monitoring.

Suitable arteries for arterial catheterization in the horse include the transverse facial, facial, and greater metatarsal arteries. In the standing horse, the transverse facial or the facial artery are most practical (Figure 6-2).

The reference unit for blood pressure is millimeters of mercury (mm Hg), meaning the force exerted by the blood against an area of the vessel wall to raise a column of mercury by a certain number of millimeters. Occasionally, centimeters of water (cm H_2O) are used. One mm Hg equals 1.36 cm H_2O. The mercury manometer is too slow, however, to record changes in blood pressure rapidly. Therefore for clinical use, a continuous method of pressure recording is preferable. A transducer transforms the pressure signal to an electronic signal that can be displayed continuously. One then can use the transducer and flush device* for continuous blood pressure measurement. One should place the transducer at the level of the heart base, as estimated by the point of the shoulder.

In addition to blood pressure measurement, invasive blood pressure measurement enables evaluation of the pressure waveform, which in turn can provide insight as to the status of the stroke volume and peripheral vascular tone.

* Catheter-over-needle, Arrow International, Reading, Pennsylvania.

† Seldinger technique transradial aretery catheter, Arrow International.

* Pressure Monitoring Kit with Truwave disposable pressure transducer, Edwards Lifescience, Irvine, California.

6.3.3 INDIRECT MEASUREMENT

Indirect blood pressure measurements depend on a cuff placed around the tail or the metatarsus. The diameter of the cuff influences the accuracy of the measurement, with cuffs that are too wide resulting in underestimation of the blood pressure. An ideal cuff width-to-circumference ratio of 0.25 to 0.35 has been recommended for use on the tail or limbs of horses. Cuff widths are available for neonate, pediatric, and adult horses. Once the cuff is in place, one measures blood pressure by recording the signal emitted by the changing blood frequency during the pulse wave. The following is a list of noninvasive blood pressure measurement methods.

6.3.3.1 Doppler

Doppler uses a small ultrasound probe placed on a peripheral artery, and a piezoelectric crystal within the probe converts the pulse wave into an audible signal. One must place the probe over a shaved area (usually under the tail of the horse) after application of a coupling gel. This method only allows measurement of systolic pressure and is therefore not as useful.

6.3.3.2 Oscillometric Sphygmomanometry

Oscillometric sphygmomanometry relies on the recording of the change in oscillations generated by the change in blood flow during deflation of the cuff. Oscillations start as the cuff pressure reaches systolic pressure, are maximal at mean pressure, and disappear when the cuff reaches diastolic pressure. The meter records and displays systolic, diastolic, and mean pressures. When placing the meter on the tail, one can use tape or a bandage below the cuff to prevent its slipping, but one should not restrain the cuff itself (Figure 6-3).

6.3.3.3 Photoplethysmography

Photoplethysmography relies on the detection of arterial volume by attenuation of infrared radiation. Photoplethysmography originally was designed for use in human fingers and has been validated for use in small dogs and cats but has not been evaluated for use in horses.

6.3.3.4 Transesophageal Ultrasound

Transesophageal ultrasound is a method of hemodynamic monitoring that uses a transesophageal probe with two ultrasound transducers.* An M-mode transducer continuously measures the aortic diameter, while a pulsed doppler measures the flow velocity, providing hemodynamic measurements including mean arterial pressure. Although transesophageal doppler† echocardiography has been evaluated for determination of 282
cardiac output in horses, the accuracy and repeatability of the combined probes for blood pressure 283
determination has not been evaluated.

Figure 6-3 Indirect oscillometric blood pressure measurement in a horse using a cuff placed on the tail.

* HemoSonic, Arrow International, Reading, Pennsylvania.

† Vingmed Sound, Horten, Norway.

6.3.4 GOALS OF BLOOD PRESSURE MEASUREMENT

The goal of blood pressure measurement is to identify hypotension and to follow the response to therapy after interventions. Blood pressures of greater than 70 mm Hg are targeted in the adult and greater than 60 mm Hg are targeted in neonates. In horses, hypertension rarely is identified other than after giving high doses of pressor agents such as phenylephrine.

6.3.5 PITFALLS

When using direct pressure monitoring, one should ensure that a good waveform is visible on the oscilloscope. Dampening of the pressure waveform by an air bubble or improper catheter placement leads to flattening of the pressure waveform and falsely low pressure measurements. Alternatively, long connector tubing lengths (>4 feet) can lead to a resonant system that records a falsely elevated systolic pressure. The flush test can help determine whether the recording system is distorting the pressure waveform.

6.3.6 BLOOD GAS ANALYSIS AND ELECTROLYTE AND LACTATE ANALYSIS

One can perform blood gas analysis easily using one of several point-of-care units. * These systems provide blood gas and electrolyte analysis. Depending on the system, ionized calcium can be part of the standard output or may require a special cartridge. Some units also report hemoglobin and hematocrit, but this is unreliable for horses because values are based on analysis of human hemoglobin. Two of the units (I-Stat and Nova) also provide lactate analysis, but this will be available shortly on the Diametrics as well. Alternatively, one can use a handheld lactate analyzer.* This unit measures plasma lactate and calculates an algorithm based on human values for whole blood. The best performance of the unit on equine plasma is measurement of lactate using the plasma mode. For all these units, carefully observing the manufacturer's instructions for sample handling and use of cartridges is essential.

* IRMA Blood Analysis System; I-Stat, I-Stat Corporation; NOVA Stat Analyzer, Nova Biomedical, Waltham, Massachusetts, www.Novabiomedical.com

* Accusport Portable Lactate Analyzer.

6.3.7 GLUCOSE

Glucose concentration is measurable in serum or whole blood. Automated chemistry analyzers use serum, whereas point-of-care glucometers† use whole blood with or without anticoagulants. Following the directives of the manufacturer is important to avoid errors. One also should keep in mind that glucose measurement made on a serum sample always will be higher than those on whole blood for the same sampling time.

6.4 Important Procedures in Adult Critical Care

Critical care for adult horses varies depending on the underlying problem being addressed. Expertise with a variety of technical procedures is advisable to facilitate diagnostic and therapeutic efforts.

6.4.1 NASOGASTRIC INTUBATION

6.4.1.1 Procedure

Nasogastric intubation is an essential and possibly lifesaving procedure performed in cases of equine colic. One should restrain the horse adequately, with a twitch and sedation if needed. The clinician should stand on the side of the horse, with the hand closest to the horse placed on the nose, with the thumb in the nostril. With the other hand, the clinician passes the tube in the ventral meatus, using the thumb to keep it directed correctly. If one encounters a hard structure, it is the ethmoidal area, and one should redirect the tube more ventrally. Once one reaches the pharynx, one feels a soft resistance. One can turn the tube 180 degrees to direct its curvature dorsally. The clinican stimulates the horse to swallow by gentle to-and-fro movement or by 283
blowing in the tube. Keeping the head of the horse flexed at the poll is helpful. Once the horse swallows, the 284
clinician pushes the tube into the esophagus. Blowing into the tube to dilate the esophagus facilitates insertion. If the horse coughs, the clinician withdraws the tube and repeats the procedure until the tube is positioned correctly. One can determine that the tube is placed correctly in the esophagus by three ways: gentle suction should elicit a negative pressure, shaking of the trachea should not elicit a rattle, or visual confirmation of correct placement. Direct observation is the safest method. One advances the tube until it is in the stomach (fourteenth rib). If one encounters difficulty in passing the cardia, one can inject 60 ml of mepivacaine into the tube. Once in place, if reflux is not spontaneous, one must cause the horse to reflux. One should never administer medication by nasogastric tube to a horse with colic without checking first for reflux. For this, one fills the tube with water using a pump and directs the end of the tube downward to verify the presence of gastric contents. Subtracting the amount pumped in from the amount obtained is useful to get net amount of reflux.

One removes the tube by first occluding it (thumb on the end or folding it) to prevent its contents from spilling out in the pharynx and possibly the trachea as it is withdrawn. One then applies gentle traction in a direction parallel to the nose. If one encounters bleeding, one can place a towel over the nose of the horse. The bleeding, even if severe, is self-limiting.

6.4.1.2 Interpretation

Nasogastric reflux is not normal. Occasionally, one obtains a small amount of reflux (1 L or less) if a horse had a tube in place for a long time. When one obtains reflux, one should note the amount, character, and timing in relation to the onset of colic. In addition, one should note the response to gastric decompression.

Typically, reflux refers to small intestinal ileus, functional or mechanical. Lesions of the proximal small intestine produce large amounts of reflux early in the onset of the colic. With lesions of the distal small intestine (ileum), one initially obtains no reflux, and as the condition persists, one obtains reflux, but usually several hours after the onset of the colic. Occasionally, large colon disease can be associated with reflux, if the colonic distention exerts pressure on the duodenum as it curves over the base of the cecum.

Foul-smelling, fermented, or bloody, copious reflux is associated with anterior enteritis. With intestinal obstruction, the reflux usually is composed of fresh feed material and intestinal secretions. Reflux originating from the small intestine is alkaline, whereas reflux composed of gastric secretions is acidic. Because outflow obstruction is rare in horses, one usually does not measure pH.

Response to gastric decompression is important information. Horses with functional ileus show relief of pain, and the heart rate decreases in response to decompression. Horses with a mechanical obstruction usually remain painful, although some horses also respond. One then must consider the rest of the examination, deciding whether functional or mechanical ileus is present. One should note the amount of reflux obtained because this factors into ongoing losses, and the volume of fluids given intravenously must be adjusted accordingly.

Horses with functional ileus need gastric decompression usually every 4 hours, although if the condition is severe, they may require decompression every 2 hours.

One should leave the nasogastric tube in place only as long as required, because some horses develop pharyngeal and laryngeal irritation associated with its presence.[15] These horses then have pain when swallowing when they resume feeding.

6.4.2 ABDOMINOCENTESIS

Abdominocentesis is important for evaluating abdominal disease, whether it is colic, weight loss, or postoperative problems. Box 6-2 provides the materials needed to perform this procedure.

6.4.2.1 Procedure

The clinician clips a 2- by 2-inch area approximately 3 cm caudal to the xyphoid, and 1 to 2 cm to the right of midline. With sterile gloved hands, one inserts an 18-gauge needle through the skin and gently advances it into the abdomen. If one does not obtain fluid, one can insert another needle next to the first one. If one obtains no fluid, one can try a bitch catheter, cannula, or dialysis catheter. Obtaining fluid from very dehydrated horses can be difficult.

To insert a teat cannula, bitch catheter, or dialysis catheter, one places a small bleb of local anesthetic at the site, punctures the skin and abdominal wall with a 15-gauge scalpel blade using sterile technique, and then 284
285
inserts the chosen device in the abdomen. One will encounter two points of resistance: as the device goes through the abdominal wall and as it goes through the peritoneum. One collects the fluid in EDTA (shaken out of the tube to avoid excessive amount in the sample) and, if the fluid is cloudy, in a culture tube.

6.4.2.1.1 BOX 6-2 MATERIALS NEEDED FOR ABDOMINOCENTESIS

18-gauge, 1½-inch needle

Teat cannula

Bitch catheter

Dialysis catheter

Sterile gloves

EDTA and culture tubes

6.4.2.2
Interpretation

Normal values for abdominocentesis are as follows: total protein, less than 2.5 g/dl, and white blood cells, less than 5000 cells/μl. On cytologic examination, neutrophils comprise approximately 40% of cells, the rest being lymphocytes, macrophages, and peritoneal cells.

With intestinal strangulation, the protein increases first (in the first 1 to 2 hours) such that the fluid is clear but more yellow. After 3 to 4 hours of strangulation, red blood cells also leak, and the fluid takes is more orange. After 6 hours or more, white blood cells increase gradually, with the progression of intestinal necrosis.

6.4.2.3
Common Problems

6.4.2.3.1
Differentiating Enterocentesis From Intestinal Rupture

Enterocentesis sometimes occurs and must be differentiated from intestinal rupture. With enterocentesis, a cytologic examination reveals plant material, bacteria, and debris, but no cells. The clinical condition of the horse is not consistent with rupture, although in early rupture, clinical signs may not reflect rupture (2 to 4 hours are necessary for manifestation of signs). Cytologic examination of abdominal fluid with intestinal rupture shows neutrophils, bacteria, and bacteria that have been phagocytized by neutrophils.

6.4.2.3.2
Differentiating Blood Contamination From Internal Hemorrhage

Blood contamination can occur from the procedure and must be differentiated from internal hemorrhage or severely devitalized bowel. Blood from skin vessels usually swirls in the sample and spins down when centrifuged, leaving the sample clear. If an abdominal vessel is punctured, blood also spins down. All fresh blood contamination shows platelets, which are not present with blood older than 12 hours. If the spleen is punctured accidentally, centrifugation reveals a packed cell volume higher than the peripheral packed cell volume. In internal hemorrhage, blood is hemolyzed such that the supernatant is reddish after centrifugation; the sample has no platelets and shows erythrophagocytosis. Ultrasonography also reveals fluid swirling in the abdomen.

Excess EDTA in the sample falsely elevates the total protein. When performing an abdominocentesis, shaking out the EDTA from the tube to avoid this sampling error is useful.

6.4.2.3.3
Differentiating Peritonitis From Normal Postoperative Changes

Abdominal surgery increases the total protein and white blood cell count for some time after surgery. Typically, if no enterotomy occurred, the white blood cell count increases greatly for 4 to 7 days and returns to normal by 14 days. The total protein may remain elevated for 3 to 4 weeks after surgery. Neutrophils appear to be nondegenerate. After an enterotomy or an anastomosis, one may see degenerate neutrophils and occasional bacteria in the first 12 to 24 hours. Subsequently, the white blood cell count remains elevated for approximately 2 weeks, but on cytologic examination the neutrophils appear to be nondegenerate and no bacteria are apparent. The total protein remains elevated for 1 month after surgery. If septic peritonitis is present, clinical signs are consistent with bacterial infection (fever, depression, anorexia, ileus, pain, endotoxemia). The white blood cell count and total protein are elevated greatly. On cytologic

examination, greater than 90% of cells are neutrophils, and they appear to be degenerate. Free and phagocytized bacteria are visible.

6.4.3 TROCARIZATION

Trocarization is useful to decompress the abdomen for abdominal compartment syndrome (severe distention associated with pain and dyspnea). Box 6-3 lists the materials needed for this procedure.

6.4.3.1 Procedure

One should perform trocarization only for large colon distention and never to decompress the small intestine. Before one decides to trocarize, identifying the segment of intestine involved is important. In adult horses, one can make such indentification by rectal palpation, and in foals or small horses, one can use radiographs or ultrasound. The distended segment of large colon also must be close to the body wall so it can be reached safely.

6.4.3.2 Method

The most common site for trocarization is the right upper flank area, just cranial to the greater trochanter at the location of the cecal base. The clinician clips, prepares, and infiltrates with a local anesthetic a 4- by 4-cm area 285
of skin. With gloved hand, one inserts a 14-g catheter with an extension tube perpendicular to the skin. One 286
places the end of the extension in water so that gas bubbles are visible when the tip of the catheter is positioned correctly. When one obtains gas, one withdraws the trocar part of the catheter slightly to avoid laceration of the bowel. The catheter may need to be repositioned several times when gas is not obtained. After decompression, one removes the trocar and infuses an antibiotic (usually gentamicin) while withdrawing the catheter.

6.4.3.2.1 BOX 6-3 MATERIALS NEEDED FOR TROCARIZATION

14-gauge, 5¼-inch catheter

Local anesthetic

Gloves

Extension tubing

Small water container (syringe case works)

Peritonitis and local abscessation are the two most common problems encountered after trocarization. One observes the horse for 24 hours for signs of peritonitis. If one suspects peritonitis, confirmation is with abdominocentesis, and one administers systemic broad-spectrum antibiotics to the horse until the condition resolves. If a local abscess develops, one can drain it externally.

6.4.4 TRACHEOSTOMY

Box 6-4 lists the materials needed for an emergency tracheostomy pack.

6.4.4.1
Preparation

If possible, one should clip, prepare, and infiltrate with local anesthetic the planned incision site. In acute respiratory distress, this may not be possible, and one makes the tracheostomy.

6.4.4.2
Procedure

One makes an 8- to 10-cm longitudinal incision at the junction of the proximal and middle third of the neck, just above the V made by the junction of the sternothyrohyoideus muscles. One must take care to stay on midline to favor drainage, separating the sternothyrohyoideus muscles on the midline and exposing the trachea. One makes a transverse incision between two tracheal rings, taking care to avoid damaging the tracheal cartilages. If the head of the horse is supported in elevation during the procedure, one should make the tracheal incision distal in relationship to the skin incision, to avoid covering the incision when the head is lowered. In emergency situations one uses a J-type tracheostomy tube because of ease of insertion. When the horse is calmed down, or if the situation is not critical, a self-retaining tube is preferable for maintenance because J-tubes tend to fall out. If the animal is to be ventilated, a silicone-cuffed tube is preferable to allow for closed-system ventilation.

6.4.4.2.1
BOX 6-4 MATERIALS NEEDED FOR AN EMERGENCY TRACHEOSTOMY PACK

Local anesthetic

Needle and syringe

Disposal blade

Scissors

Hemostats

J-type tracheostomy tube

6.4.4.3
Maintenance and Removal

One should clean the tracheostomy tube daily and change it as needed. Petroleum gel applied around the incision prevents skin scalding. In general but particularly in foals, one should remove tracheostomy tubes as early as possible to avoid permanent tracheal deformity. To help decide when to remove the tube, one can occlude the tube temporarily to see if the horse can breathe without it. Once removed, one cleans the site of exudate twice daily and allows it to heal by second intention. The wound generally closes down in 10 to 14 days and heals in 3 weeks.

6.4.5
PLACEMENT OF A CHEST TROCAR

Thoracic drainage is an essential part of managing pleural effusion and can be lifesaving in cases of severe effusion. Pleural effusion is identified by typical increases in area of cardiac auscultation, dullness in the ventral area of auscultation, and if unilateral, a discrepancy in auscultation between the two hemithoraxes. One can use percussion, although typically ultrasound provides the best method of identifying fluid in the chest. One can

drain pleural fluid through a cannula or by placement of a chest drain. Chest drains are placed in the seventh intercostal space approximately 2 inches above the elbow joint. The clinician clips, prepares, and infiltrates the site with a local anesthetic. One makes an incision in the skin cranial to the proposed point of entry and inserts the trocar through the skin. One moves the incision in a caudal direction to a point between two ribs and using pressure pushes the trocar into the chest. One hand serves as a stop to control depth of entry. Once one obtains fluid, one places a Heimlich valve on the end of the tube and sutures the tube in place using a Chinese finger trap pattern.

6.4.6 PNEUMOTHORAX

Pneumothorax (air in the pleural cavity) is classified as open (external wound) or closed. The pleural pressure equilibrates with atmospheric pressure, resulting in lung collapse. Tension pneumothorax develops when air continuously enters the chest without evacuation. The pleural pressure can reach supraatmospheric levels and can be life-threatening. 286

287

In open pneumothorax, sealing of the chest must occur, followed by evaluation of air. One can seal the chest with sheets of plastic wrapped around the site of entry or close the wound if possible. One evacuates the chest by placing a small trocar, or a 14-gauge catheter, in the dorsal twelfth intercostal space, removing the trocar once the air has been evacuated satisfactorily.

In closed pneumothorax or tension pneumothorax, one must leave the catheter in place until the source of air entry can be sealed.

6.4.7 URINARY CATHETERIZATION

Measurement of urine output in adult horses is an infrequent procedure, compared with foals, but may be useful in instances of oliguric renal failure or when 24-hour volumetric measurements are needed. Male horses with neurologic disorders that make them unable to express their bladder may require bladder decompression.

In the mare, one achieves urine collection easily by placing a Foley catheter that is connected to collection tubing. One can make a closed system by using a solution administration set and empty fluid bag. In geldings, one can insert a male urinary catheter and suture it in place using a Chinese finger trap. If the horse is recumbent and thrashing, leaving as little of the catheter protruding to avoid it being pulled out is important. Normal horses produce 1 to 2 ml/kg/hr of urine.

6.4.8 CARE OF THE DOWN HORSE

Nursing care is an essential component of successful recovery of down horses. For a favorable outcome, identification of a disease process that has a potential for recovery in a short period (days to weeks) is important. Care of down horses is time consuming and is more difficult if the horse is heavy. Mechanical ventilation of down adult horses has a high failure rate because of complications. The down horse requires fluid and nutritional support, evacuation of the intestinal and urinary tracts, prevention of eye trauma, and management of decubital ulcers.

Recumbent horses usually have decreased maintenance fluid requirements, because they are for the most part inactive, are kept at a reasonable ambient temperature, and usually have decreased feed intake. A lower maintenance fluid rate (40 ml/kg) suffices in these horses and can be provided by allowing the horse access to water (if the horse remains sternal for short periods), by using a preplaced feeding tube, or by using intravenous

fluids. For the short term, intravenous fluids are convenient, but the risk of thrombophlebitis is higher with prolonged catheterization.

One can feed the recumbent horse by allowing the horse to eat (this is possible if mental status is minimally affected), by nasogastric intubation, or by partial parenteral nutrition. If one uses nasogastric intubation, one can prepare a slurry of pelleted feed to facilitate administration. Importantly, one must ensure correct placement of the tube before feed administration, particularly in dysphagic horses. Partial parenteral nutrition of glucosed-based solutions is well tolerated in adult horses and obviates the need for oral feeding. One must ensure strict asepsis of all lines, because these solutions are rich in glucose.

Figure 6-4 Recumbent horse with a head bandage to protect the eyes from injury.

Recumbent horses are often reluctant to urinate or defecate, at least initially. Colic caused by impaction or tympany is a common complication. To obviate this, one should empty the rectum regularly and administer mineral oil to facilitate gastrointestinal transit. Most horses learn to urinate while recumbent, but initially, one must empty the bladder 2 to 3 times daily. Horses that cannot urinate require placement of a urinary catheter.

Decubital ulcers at pressure points (elbow, point of the shoulder, tuber coxae, hip, hocks, zygomatic arch) are difficult to avoid in recumbent horses. Adequate padding, frequent (every 4 hours) turning, and changing from sternal to lateral recumbency can be helpful in delaying the onset of decubital ulcers. Bandaging of the lower legs can be useful in thrashing horses to minimize injury.

Adequate eye cleaning and lubrication are essential in the recumbent horse. Debris often accumulates in the dependent eye, which can cause ulceration. One should clean the eye frequently using ophthalmic solution and should apply lubrication. In horses that are recumbent for prolonged periods, bandaging of the head is useful to prevent eye injury (Figure 6-4).

7 CHAPTER 7 DISORDERS OF THE RESPIRATORY SYSTEM

Dorothy M. Ainsworth

Richard P. Hackett

Disorders of the respiratory system are second in importance only to those of the musculoskeletal system in limiting the athletic performance of the horse. Owners sustain major economic losses when respiratory diseases interrupt the training programs of horses or when horses must be retired because of lung damage sustained from respiratory disease. Thus early detection and treatment of respiratory problems is essential for the rapid return of athleticism to performance animals.

7.1 Diagnostic Approach to Respiratory Disorders

7.1.1 HISTORY

The clinician should direct questions to the person most familiar with the performance and medical history of the horse. Accurately defining the problem, devoid of subjective impressions, can be the most difficult part of taking the history.

7.1.1.1 Age and Breed

The age and breed of the animal exhibiting respiratory-related signs may provide clues as to the problem. Congenital defects (nasal septal deviations, choanal atresia, subepiglottic cysts, and hypoplastic lungs) are typically evident at birth, whereas other conditions, such as chronic bacterial pneumonia *(Rhodococcus equi),* may not be evident until the foal is older (1 to 3 months of age). Viral and bacterial upper respiratory tract infections tend to occur in the weanling and yearling, whereas conditions such as inflammatory airway disease, pleuropneumonia, or exercise-induced epistaxis are found more commonly in performance horses 2 years or older. In contrast, recurrent airway disease (heaves) or neoplasia of the respiratory tract are diagnosed primarily in the middle-aged or older horse.

Considering the breed of the horse is also important in investigating respiratory disorders. For example, one should evaluate Arabian foals with chronic infections for combined immunodeficiency syndrome, a heritable condition in which cell-mediated and humoral limbs of the immune system are deficient. In addition, solitary defects in the humoral immune system also predispose horses to develop chronic respiratory and enteric infections. Selective immunoglobulin M (IgM) deficiency tends to occur more frequently in Arabians and Quarter Horses, whereas agammaglobulinemia has been documented in Thoroughbreds and Standardbreds.[1,2]

290

7.1.1.2 Environment

One should ascertain the environment to which the horse was or presently is exposed. For example, is the horse stabled at a racetrack where population turnover is high and the potential for viral respiratory outbreaks is increased, or is the horse a sole inhabitant of a small pasture, seldom exposed to other horses? Does the farm have a history of endemic infections, as often occur with *Streptococcus equi* outbreaks? Has the horse been exposed to pastures grazed by donkeys? This, along with information regarding the diet (hay, pelleted rations, or pasture), the nature of the bedding materials (straw, peat, or shavings), and the amount of time the horse is

stabled are important considerations in establishing the risk factors for some respiratory disorders such as recurrent airway obstruction or lungworm infections. One also should obtain the deworming and vaccination schedules. Young horses are at risk for developing verminous pneumonia resulting from *Parascaris equorum* migration. Nematode eggs can survive for prolonged periods on a pasture. Thus establishing whether the foal was exposed to pastures grazed by yearlings or 2-year-olds may help in establishing the diagnosis and treating the problems. If the horse is a performance animal and is at an increased risk for developing upper respiratory tract infections, one should determine how frequently equine influenza and equine herpesvirus type 1 (EHV1) and type 4 (EHV4) vaccinations are administered.

7.1.1.3 Prior Medical Problems

Has the horse had a previous history of illness or trauma that might be related to the present complaint? Viral respiratory conditions often precede the development of bacterial pneumonia. Sequelae to *S. equi* infections include internal abscessation, guttural pouch empyema, retropharyngeal abscesses, and purpura hemorrhagica, which ultimately may affect the respiratory and cardiovascular systems. Trauma may be implicated in the development of diaphragmatic herniae, pneumothorax, or tracheal injury and subsequent stricture formation.

7.1.1.4 Present Medical Problem

The clinician should direct questions to define the exact problem, establishing the chronicity of the disorder and the rapidity of its development. Is the problem insidious in onset or an acute disorder of less than 2 weeks' duration? Is the onset associated with a stressful event such as racing or a prolonged van ride? Does the farm have new arrivals that have not been quarantined? One should also determine the effect of the respiratory complaint on the expected athletic performance: Are clinical signs evident during eupneic (resting) breathing or only noticeable during the hyperpnea of exercise? Has the horse received any medication and did the clinical condition improve? Amelioration of signs during therapy suggests that the previous treatment protocols were not of sufficient duration or that an underlying immunodeficiency exists.

7.1.2 PHYSICAL EXAMINATION

Before examining the horse, simply stepping back and evaluating the demeanor and mental status (alert or depressed), posture, and manner of movement of the horse is helpful. Has the horse adopted a particular stance (extended head and neck), or is it reluctant to move because of pain (pleurodynia)? Are changes in the pattern of breathing from the normal eupneic state obvious (Box 7-1)? Is the breathing pattern rapid and shallow? Does nostril flaring accompany a pronounced expiratory effort? The normal respiratory rate of the adult horse varies from 8 to 15 breaths per minute, with a slightly noticeable abdominal component during expiration (an active process in the horse).

Abnormalities of the respiratory system are evident also by the production of unusual sounds associated with respiration; the presence of a cough; a nasal or ocular discharge; lymphadenopathy; epistaxis; facial, pharyngeal, or cervical swellings; and cyanotic mucous membranes. Ataxia or reluctance to move, the presence of ventral thoracic or limb edema, foul odors associated with breathing, and a history of weight loss may occur with respiratory disorders.

7.1.2.1 BOX 7-1 BREATHING PATTERNS

7.1.2.1.1 Eupnea

The normal quiet and seemingly effortless breathing pattern adopted by the healthy horse at rest. Inspiration and expiration in the horse are active processes.

7.1.2.1.2 Tachypnea

A breathing pattern characterized by rapid frequency and shallow depth or small tidal volume.

7.1.2.1.3 Hyperpnea

A breathing pattern characterized by an increase in the depth and rate of breathing, as might be found during exercise.

7.1.2.1.4 Apnea

A period of time in which no discernible respiratory effort is made and air flow has ceased. Apnea may accompany sleep-related disorders or excessive ventilation (hypocapnia-induced apnea).

7.1.2.1.5 Hypoventilation

A pattern of breathing that alters gas exchange sufficiently to cause hypercapnia or elevations of arterial carbon dioxide tension.

7.1.2.1.6 Hyperventilation

A pattern of breathing that increases alveolar ventilation and results in arterial hypocapnia.

7.1.2.1.7 Dyspnea

A breathing pattern that appears to reflect difficulty in breathing. The animal appears to be distressed, and increased work of breathing is obvious. 290

291

The clinician should assess the airflow from both nostrils to rule out potential obstructions or masses within the nasal cavity. One can detect atheromata, which may restrict airflow during exercise, by palpating the false nostrils. Any peculiar breath odors are detectable at this time. Percussion of the frontal and maxillary sinuses, performed by gently tapping over the sinuses while one holds the mouth of the horse slightly open, may reveal a dullness because of accumulations of fluid or inflammatory products, but the absence of a percussable change does not rule out a sinus disorder. One also should determine evidence of swelling in the submandibular space (lymphadenopathy) or in the pharyngeal (guttural pouch or retropharyngeal disorders) and cervical areas (accessory lungs[3]). Palpation of the larynx and trachea is routine and should not elicit coughing episodes in the normal horse. One also can detect evidence of muscle atrophy or prior surgeries (laryngoplasty, laryngotomy, myotomy) during the physical examination of the upper respiratory tract. One should check for patency of the jugular veins (thrombophlebitis and secondary pulmonary abscessation) or for evidence of perivascular

injections that may contribute to upper respiratory tract obstructions by involving the recurrent laryngeal nerve or vagosympathetic trunks.

The clinician then should conduct a complete physical examination, paying attention to all organ systems (and not simply focusing on the respiratory system). In respiratory emergencies, one conducts an abbreviated initial examination and directs efforts at patient stabilization until that time when a more thorough physical examination can be conducted.

7.1.2.2 Auscultation of the Lung Fields

The clinician should examine the horse during eupneic and hyperpneic (by use of a rebreathing bag) breathing patterns. Normal *breath sounds* are those produced by turbulent air movement through the tracheobronchial tree and vary in intensity and quality depending on the portion of the lung field auscultated. The *vesicular sounds,* over the middle and diaphragmatic lung lobes, are the quietest sounds; the *bronchial sounds,* over the trachea and the base of the lung, are the loudest.[4–6] In the normal horse one can hear breath sounds more easily on the right side than on the left. Considerable variation exists between normal patients in the intensity of the breath sounds. For example, vesicular sounds are often barely audible during eupneic (normal) breathing in the obese patient and are perceived as soft rustling sounds. However, one may hear breath sounds easily in the thin or young animal because of less attenuation of lung sounds by the chest wall. The intensity of breath sounds also increases with increased airflow. Thus breath sounds are accentuated in febrile or excited animals or in animals hyperpneic from a variety of causes (exercise, hypoxia, pain). However, auscultatory findings do not always correlate well with the degree of alveolar ventilation.[5] For example, in horses with lung consolidation the transmission of breath sounds from adjacent areas gives the false impression that that region is well ventilated. Breath sounds also may become more difficult to hear in cases of (1) alveolar overinflation in which the aerated tissue of the lung is a poor conduction medium of sound or (2) pneumothorax and pleural effusions in which the sound is reflected at the pleural surface (acoustic impedance).[5]

Adventitious lung sounds are abnormal sounds superimposed on the normal breath sounds and have been described as crackles or wheezes. Crackles are short, explosive, discontinuous sounds that have been likened to the sound of salt thrown in a hot frying pan or the sound of cellophane being crumpled. They are usually of low intensity and are audible during the inspiratory phase of respiration. Their production has been attributed to the sudden equalization of pressure in two compartments after airways have reopened. Crackles are audible in cases of interstitial pneumonia and pulmonary edema (restrictive pulmonary diseases) and in cases of bronchopneumonia or airway diseases (obstructive disorders). Breathing 100% oxygen also may produce crackles because the nitrogen stent maintaining alveolar distention is eliminated.[7] Crackles are also audible in cases of subcutaneous emphysema. Wheezes are musical sounds thought to arise from the vibration of airway walls or tissue masses in close contact with the airway walls and may be audible during inspiration or expiration. Wheezes may be monophonic or polyphonic, the latter indicative of multiple sites of airway obstruction. Pleuritic friction rubs have been described as sandpaper-like sounds generated by the movement of the visceral and parietal pleurae across each other. One may detect them (infrequently) in the early stages of “dry” pleuritis, before the effusive stage.

7.1.2.3 Percussion of the Thorax

One percusses by methodically tapping the intercostal spaces of the thorax using a plexor and pleximeter (foals) or a large spoon and neurologic hammer (adults) and evaluating the nature of the sound produced. Aerated tissues produce a resonant sound, whereas fluid-filled structures (bowel, heart, lung abscesses,

consolidated lung) produce a dull sound. One should identify the transitional site where sound quality changes during percussion by using a piece of tape. One then compares the limits of the percussed field with those of the normal horse. The cranial limit is the shoulder musculature, the dorsal limit is the back musculature, and the caudoventral limits are the seventeenth intercostal space at the level of the tuber coxae, the sixteenth intercostal space at the level of the tuber ischii, the thirteenth intercostal space at the midthorax, the eleventh 291
intercostal space at the level of the scapulohumeral articulation, and the sixth intercostal space at the 292
olecranon.[8] Thoracic percussion should not be painful: resentment by the horse may indicate pleuritis or rib fractures. A ventral dullness suggests pleural effusion, pleural thickening, lung consolidation, or pericardial effusion. Occasionally, caudal borders may be expanded, suggesting alveolar overinflation, which may accompany recurrent airway disease.

7.1.2.4 Endoscopy

Fiberoptic endoscopy provides an invaluable method for assessing the equine respiratory tract. Endoscopy is helpful in establishing (1) the origin of respiratory noises that accompany laryngeal hemiplegia, dorsal displacement of the soft palate, epiglottic entrapment, rostral displacement of the palatopharyngeal arches, arytenoid chondritis, tracheal collapse or stenosis, and pharyngeal narrowing; (2) the existence of congenital defects such as subepiglottic cysts, cleft palate, or choanal atresia; (3) the source of exudate or hemorrhage occurring with guttural pouch mycosis or empyema, ethmoidal hematoma, pulmonary epistaxis, retropharyngeal abscessation, and chronic pulmonary disease; and (4) in extracting foreign bodies from the tracheobronchial tree. Videoendoscopic examination of the upper respiratory tract during maximal treadmill exercise (12 to 14 m/sec) is a routine diagnostic modality at many referral centers, allowing visualization of dynamic collapse of the upper airway structures during exercise in certain pathologic conditions. Accumulations of mucopurulent exudate within the pharynx or the trachea following exercise are compatible with a diagnosis of inflammatory airway disease. Endoscopy is a potential means of obtaining tracheobronchial aspirates (guarded swabs or catheters).[9] A number of different fiberoptic endoscope models are available but an 11-mm (outer diameter) endoscope usually is used in adult horses, and a smaller, 7.8-mm (outer diameter) pediatric scope is recommended for foals.

7.1.2.5 Sinuscopy

Sinuscopy, direct examination of the interior of the paranasal sinuses using an endoscope or an arthroscope that is introduced through a small trephine opening, is useful for diagnosing or treating sinus disease.[10,11] In selected cases, sinuscopy may be a diagnostic or therapeutic alternative to flap sinusotomy. One can access the caudal maxillary sinus at a point 2 cm rostral to the midpoint of a perpendicular line drawn from the medial canthus of the eye to the facial crest. One can access the rostral maxillary sinus 2 cm caudal to the midpoint of a line drawn from the rostral end of the facial crest to the infraorbital foramen. The frontoconchal sinus is accessible through a portal placed 40% of the distance of a perpendicular line drawn from 0.5 cm caudal to the medial canthus from the midline. The frontoconchal site affords excellent visualization of the frontoconchal sinus and, via the large frontomaxillary opening, the caudal maxillary sinus. Following sedation of the horse and surgical preparation and local anesthesia of the selected site, the clinician makes a small skin incision and opens the bone with either a ¼-inch Steinman pin (for a 4-mm diameter arthroscope) or a 10-mm trephine (for a 9-mm endosocope). The endoscope provides better illumination and a greater field of view. In addition to direct examination of the sinus interior for diagnosis (Figure 7-1), sinuscopy allows the examiner to biopsy tissues under direct visualization and to apply therapeutic procedures such as formalin injection of mass

lesions (Figure 7-2), cyst removal, and removal of sequestered bone fragments. Following examination, the clinician may close the portal with cutaneous sutures or leave it open for therapeutic lavage.

7.1.2.6 Computed Tomography

Interpretation of conventional radiographs of the equine head is notoriously difficult because of the complex anatomy and the spectrum of radiographic densities: air, soft tissue, bone, and tooth. Thus radiographs and clinical examination may not define accurately the location and extent of lesions in the head region.[12] 292
Computed tomography uses a rotating, highly columnated x-ray beam to generate digital cross-sectional 293
images.[13,14] These cross-sectional images afford a much better evaluation of normal and pathologic anatomy than can be achieved through conventional radiographs (Figure 7-3). Additionally, the digital format enables three-dimensional reconstruction of structures and manipulation of images to optimize interpretation (Figure 7-4). Constraints for this technique are its expense, limited availability, and the need for general anesthesia of the horse.

Figure 7-1 Sinuscopic view of the caudal maxillary sinus in 16-year-old Thoroughbred gelding with a history of epistaxis. A large fungal colony is on the infraorbital canal, and several small blood clots are visible. (Courtesy R.P. Hackett, Ithaca, New York, 2001.)

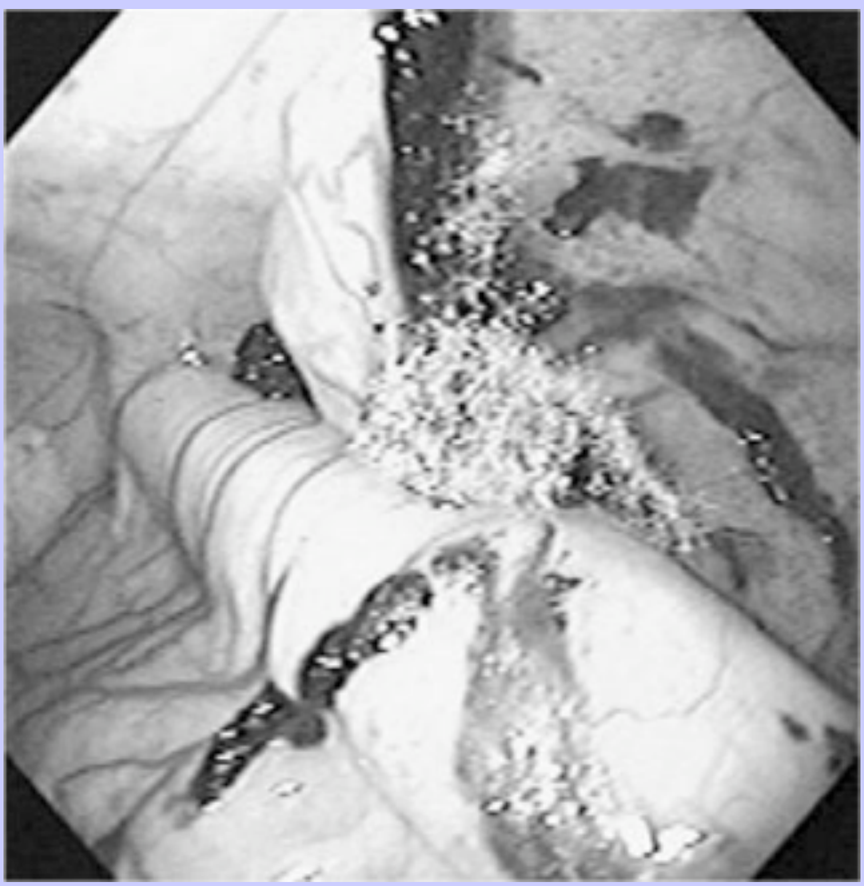

Figure 7-2 Sinuscopic view of small ethmoidal hematoma in 12-year-old Thoroughbred gelding. This lesion was injected with formalin transendoscopically. (Courtesy R.P. Hackett, Ithaca, New York, 2001.)

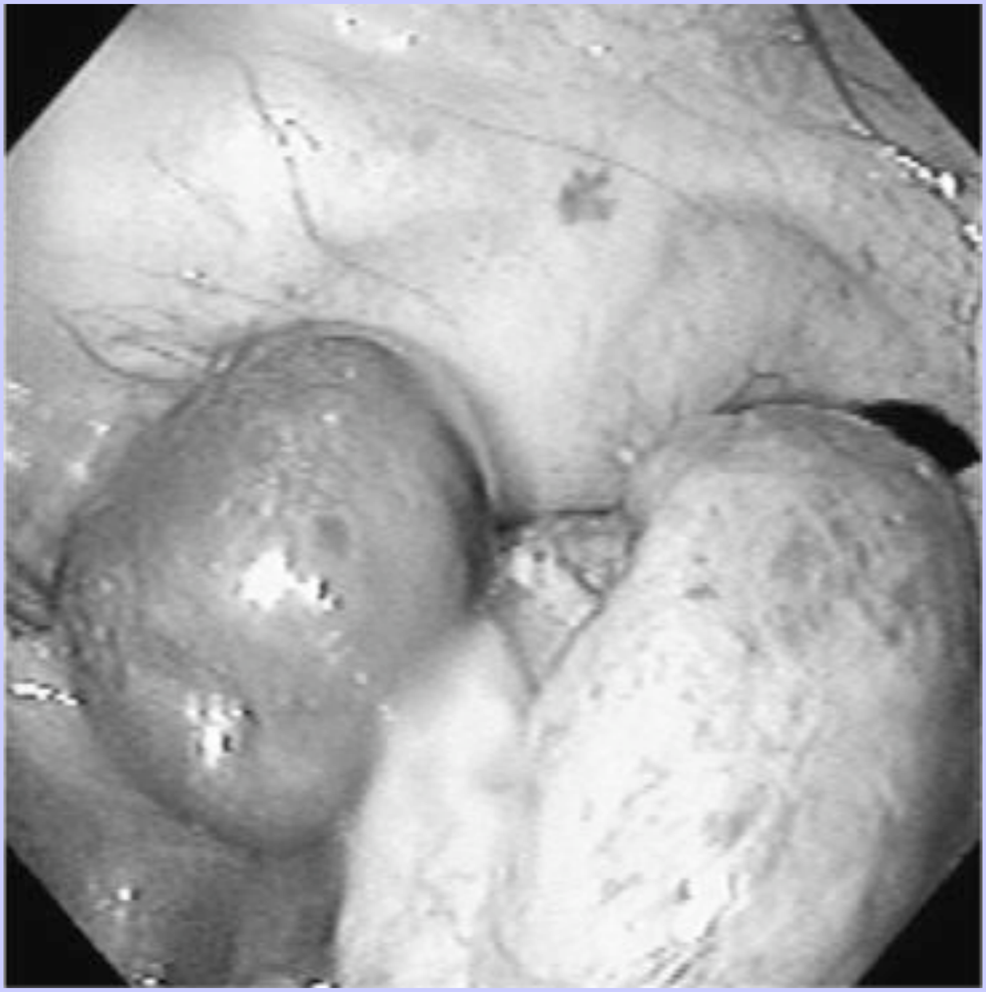

Computed tomography has proved particularly useful for examining the anatomically complicated structures such as the nasal turbinates, paranasal sinuses, teeth, nasopharynx, and guttural pouches and for evaluating areas obscured by overlap of adjacent structures on conventional radiographs (Figure 7-5). Improved evaluation of these structures has enhanced considerably the diagnosis, the selection of surgical approaches, and the ability to render an appropriate prognosis.

Computed tomography has been of limited usefulness in evaluating the lower respiratory tract structures in adult horses because of the size constraints of the gantry. However, computed tomography is an excellent diagnostic modality for detecting and defining the extent of pulmonary or mediastinal masses in the thorax of foals, ponies, and miniature horses.[15]

Figure 7-3 Cross-sectional image of an amelioblastoma involving the upper left premolars of a 4-year-old Warmblood gelding. A large soft issue mass is encroaching on the nasal passages, and significant osseous destruction of the hard palate, ventral concha, and premaxilla is visible. (Courtesy R.P. Hackett, Ithaca, New York, 2001.)

7.1.2.7 Sampling of Respiratory Tract Secretions

7.1.2.7.1 Centesis of the Paranasal Sinuses

The clinician can perform centesis of the paranasal sinuses when radiographic or computed tomographic examination reveals fluid lines or soft tissue densities in the sinuses. One performs the technique aseptically using local anesthesia on the sedated horse, using a Steinmann pin for the initial puncture of the sinus. One enters the rostral maxillary sinus at a site 2.5 cm dorsal to the facial crest and 2.5 cm caudal to the infraorbital foramen. One enters the caudal maxillary sinus (which communicates with the frontal sinus) at a site 2.5 cm dorsal to the facial crest and 2.5 cm rostral to the medial canthus. The clinician should submit aspirates for cytologic examination and bacterial culture.

7.1.2.7.2 Guttural Pouch Catheterization and Culture of the Exudate

One performs guttural pouch catheterization in cases of empyema, chondroids, or distention of the pouches. With the horse sedated, the clinician passes a fiberoptic endoscope into the guttural pouch using the biopsy instrument or a Chambers catheter as a guide for the endoscope. One obtains a sample of the exudate with a triple-guarded catheter or protected swab. A technique for obtaining percutaneous aspirates of the guttural

pouches recently has been described, but the authors prefer to use endoscopic visualization for sample collection.[16] Cytologic examination of guttural pouch aspirates from normal horses demonstrates the presence of mucus; a predominance of ciliated columnar epithelial cells; neutrophils; and a few (<1%) macrophages, lymphocytes, and eosinophils. Aspirates are not normally sterile: common bacterial isolates include α-hemolytic *Streptococcus, Staphylococcus,* and *Moraxella* species.[17] *Streptococcus equi* is not a normal inhabitant of the guttural pouch. 293 294

Figure 7-4 Three-dimensional reconstruction of the premaxilla in Figure 7-3. The extent of osseous destruction of the hard palate can be delineated clearly, as can separation of the second and third premolars. (Courtesy R.P. Hackett, Ithaca, New York, 2001.)

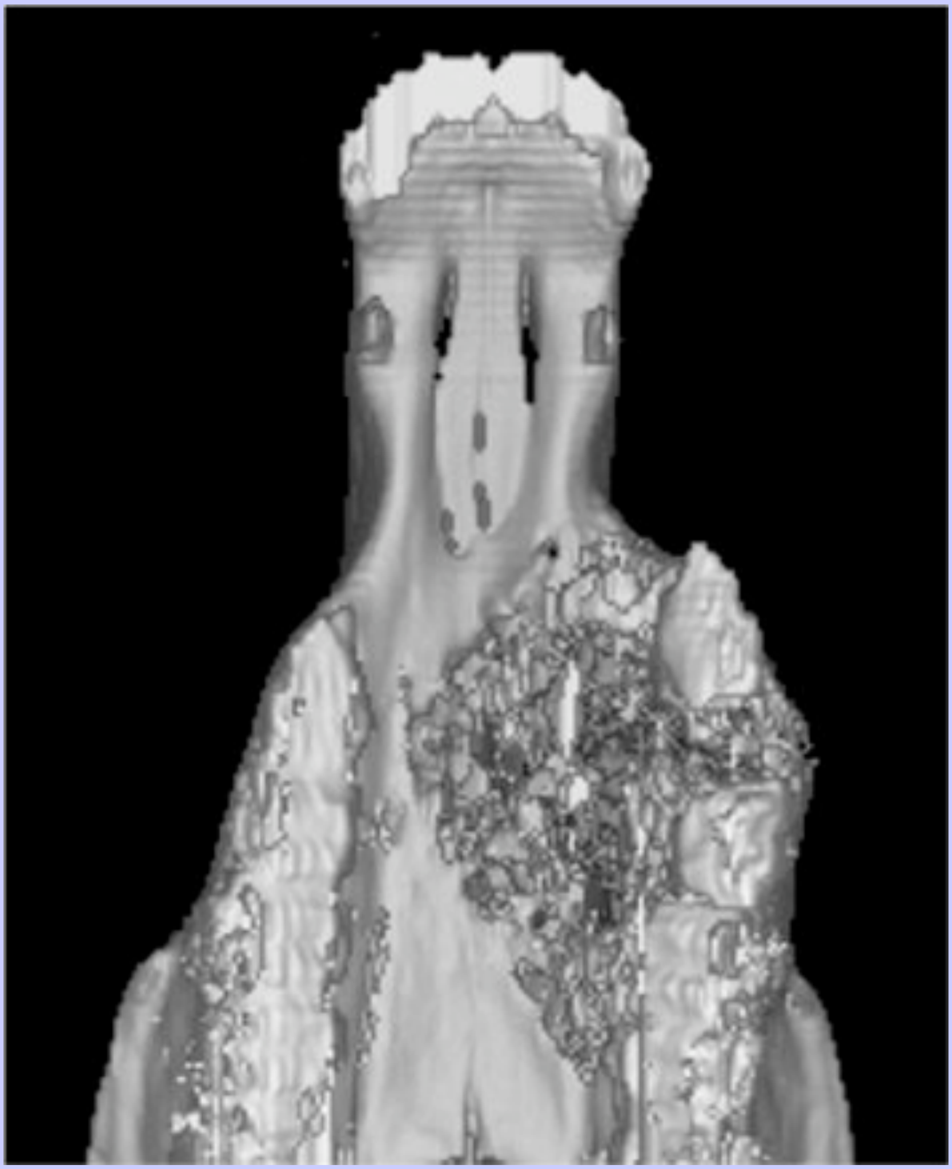

Figure 7-5 Cross-sectional image of an adenocarcinoma affecting the ethmoid turbinate in a 23-year-old hinny. (Courtesy R.P. Hackett, Ithaca, New York, 2001.)

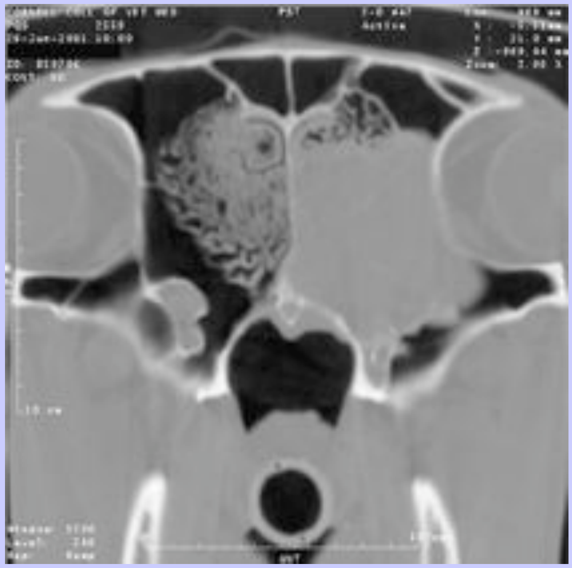

In horses suspected of having guttural pouch epistaxis, one should exercise caution regarding catheterization or endoscopic examination of the pouch. The procedure may dislodge a blood clot and cause fatal hemorrhage.

7.1.2.7.3 Sampling of Tracheobronchial Secretions

Several techniques have been advocated for obtaining tracheobronchial samples. The site of the collection sample (tracheal versus bronchoalveolar) depends on the nature of the respiratory disorder. The appropriateness of using tracheal samples to evaluate chronic inflammatory disorders has been challenged, because little correlation exists between tracheal and bronchoalveolar lavage cytologic findings or between tracheal and pulmonary histopathologic findings.[18,19] In contrast, a good correlation exists between bronchoalveolar lavage cytologic findings and pulmonary histopathologic findings.[20] Bronchoalveolar lavage is indicated in the investigation of chronic *inflammatory* diseases but may be performed with collection of transtracheal aspirates if one cannot dismiss an infectious process. Table 7-1 shows representative cytologic findings from bronchoalveolar lavage studies of normal horses. Sedation of horses before bronchoalveolar lavage is recommended. Using a fiberoptic endoscope (permitting direct visualization of the lung segment to be lavaged) or using a thick-walled flexible tube with a cuffed end (which is passed blindly into the distal airways), the clinician instills 100 to 500 ml of physiologic saline solution within the pulmonary segment. One can retrieve 50% to 75% of the fluid and examine it cytologically. Before lavage, one may instill 20 to 40 ml of 2% lidocaine to desensitize the airways.

In the absence of a suitable method for collecting bronchoalveolar lavage fluid aseptically, tracheobronchial aspirates remain the method of choice for investigation of *infectious* lower respiratory tract disorders.

Collection of culture samples by fiberoptic endoscopy simplifies the procedure and eliminates some of the complications formerly associated with the transtracheal technique, such as cellulitis and pneumomediastinum. Guarded tracheal swabs[21] and the telescoping plugged catheter of Darien[9] are convenient techniques for obtaining representative samples. However, oropharyngeal contamination still may occur when one obtains tracheobronchial aspirates endoscopically using telescoping plugged catheters.[22,23] The authors prefer to obtain tracheobronchial aspirates percutaneously.

Characterization of the normal bacterial isolates from tracheobronchial aspirates in healthy horses has been 294
well documented. When examining a horse with suspected respiratory disease, one must evaluate culture 295
results in light of the cytologic findings and clinical examination. The tracheobronchial aspirates of approximately 8% of normal horses (pastured or stabled) were found to be culture-positive for *Klebsiella,* β-hemolytic streptococci, *Pasteurella* species, and *Pseudomonas aeruginosa*. For a microorganism to be implicated in a lower airway disorder, one would expect (1) to obtain a moderate to heavy growth of the organism on culture ($\geq 1 \times 10^3$ colony-forming units); (2) to identify organisms within phagocytic cells; and (3) to have evidence of degenerative neutrophils. In contrast, anaerobes, which are a normal component of the oropharyngeal flora, normally are not isolated from aspirates of healthy horses, emphasizing their importance in diseased processes when recovered from respiratory cases. Based on their studies, Sweeney, Beech, and Roby[24] also have described a group of transient bacterial flora of questionable pathogenicity such as *Enterobacter, Bacillus, Acinetobacter*, α-hemolytic streptococci (except for *Streptococcus pneumoniae* type 3), and *Staphylococcus epidermidis,* which may be isolated from tracheobronchial aspirates. In contrast, *S. pneumoniae* now is recognized as a pathogen of the respiratory tract in horses.[25–27] Fungal hyphae may be found free or engulfed within mononuclear cells in normal horses.

TABLE 7-1 Differential Counts in Bronchoalveolar Lavage Fluid[*]

NEUTROPHILS	MACROPHAGES	LYMPHOCYTES	EOSINOPHILS	MAST CELLS	EPITHELIAL	REFERENCE
8.9 ±1.2	45.0 ±2.8	43.0 ±2.7	<1.0	1.2 ±0.3	3.5 ±0.7	18
5.0 ±4.0	72 ±10	18 ±3.0	2.0 ±4.0	1.0 ±1.4	—	20
6.2 ±5.0	70.3 ±15.2	7.6 ±3.9	1.0 ±1.4	0.6 ±1.4	14.3 ±13.4	516

* Percent of total white blood cell count plus-or-minus standard error or standard deviation.

7.1.3 RADIOGRAPHY

Radiographs may be helpful (1) in detecting soft tissue masses (abscesses, granulomata, neoplasms, hematomas, polyps) or fluid accumulations within the paranasal sinuses, the nasal cavity proper, the guttural pouches, and the retropharyngeal areas; and (2) in evaluating orofacial deformations or fractures following trauma. Radiography also allows assessment of the anatomic dimensions of the pharyngeal and laryngeal structures (thickened soft palate, hypoplastic epiglottis, hyoid bone fractures). When one suspects nasal or sinus disorders, one should take lateral, dorsoventral, and oblique views. The clinician usually can achieve proper restraint of the horse for positioning of the cassette with xylazine, detomidine, or butorphanol sedation. In the horse that one can anesthetize safely, one may obtain a more thorough definition of the extent of nasal and upper respiratory tract diseases using computed tomography scans (see the previous discussion).

Radiographic evaluation of the equine thorax remains preferable to ultrasonography for detecting diffuse parenchymal diseases such as interstitial pneumonia, pulmonary edema, and chronic airway disorders or for detecting mediastinal or deep parenchymal abscesses.[28] Imaging the thorax of the standing horse requires three to four overlapping lateral radiographs. However, compared with human or small animal medicine, in which correlations between the pulmonary disorders and the radiographic findings are well-established, the radiographic changes in equine respiratory disorders tend to be rather nonspecific. In addition, many pulmonary diseases such as inflammatory airway disease, exercise-induced pulmonary hemorrhage, lungworm infections, and recurrent airway obstruction may be associated with normal radiographs.[29]

Four types of radiographic patterns have been described: an alveolar (airspace), an interstitial, a bronchial, and a vascular pattern. In the alveolar pattern, opaque areas coalesce and completely obliterate the vessels and bronchi. Air bronchograms may be notable. This pattern occurs with pulmonary edema, hemorrhage, lung consolidation, or neoplastic infiltration. Interstitial patterns are found most commonly and are associated with a variety of conditions. This pattern causes a blurring of the edges of the pulmonary vessels, a diffuse increase in lung opacity, and variable reticular, linear, or nodular opacities.[29,30] A reticular pattern occurs with viral, bacterial, or parasitic pneumonia; pulmonary edema; interstitial pneumonia; and pulmonary fibrosis. An irregular linear pattern occurs with resolving bronchopneumonia, and a nodular pattern occurs with abscesses, granulomata, or neoplasms. Bronchial patterns alone are not found commonly but usually occur in association with interstitial patterns. Paired linear opacities or numerous small circular opacities represent thickening of the large- and medium-sized airways or of the septa around the lobules. This pattern occurs in cases of equine bronchitis and 295
bronchiolitis. Variations in the size, shape, and number of the pulmonary vessels cause a vascular pattern and 296
may be visible in horses following exercise or in horses with left-to-right cardiac shunts.

Extraparenchymal disorders that are evident radiographically include the presence of free pleural fluid or of free gas (pneumothorax) represented by the separation of the right or left or both caudal lung lobes from the dorsal and dorsolateral body wall by a free-air density.

7.1.4 ULTRASONOGRAPHY

Thoracic ultrasonography is useful for diagnostic, therapeutic, and prognostic evaluation of peripheral parenchymal lung or pleural disorders. Unlike thoracic radiography, which requires technology limited to specialty practices or veterinary medical teaching hospitals, ultrasonography is a method readily available to the practicing veterinarian. Ultrasonography is considered to be superior to thoracic radiography for detecting pleural effusion, pulmonary consolidation, pulmonary or mediastinal abscesses, tumors, or granulomata[28] and should be performed when clinical examination or thoracic percussion reveals pain and areas of dullness within the thorax.

Normal lung tissue reflects the ultrasound beam, producing an echogenic pulmonary periphery (thin white line) and reverberation artifacts or concentric equidistant echoes. Normal pleural fluid appears as an anechoic (black) area separating the parietal pleura from the lung tissue, and one commonly detects a small amount of pleural fluid in the ventral thorax of racehorses.[31] In respiratory disorders, one may detect accentuated amounts of anechoic or hypoechoic (gray) pleural fluid. The clinician can determine the character of the pleural fluid, the presence of fibrin or gas, the degree of loculation, and the existence of pleural adhesions during the examination. Pulmonary abscesses appear in ultrasonography as encapsulated cavitated areas filled with fluid or echogenic (white) material, whereas areas of pulmonary consolidation appear as dense patterns of homogeneous internal echoes with a gray tone.[32] Depending on the degree of consolidation, one may visualize bronchial and vascular

structures more easily on the sonogram, as well as mediastinal masses. Detection of caudal mediastinal masses improves when pleural effusion is concurrent, because the aerated caudal lungs impair examination. One may visualize masses located in the cranial mediastinum at the third right intercostal space in the absence of pleural effusions.

Diagnostically, certain limitations are inherent in ultrasonography. One may not detect a deep parenchymal lesion if the overlying aerated lung reflects the ultrasound beam. In addition, cases of pneumothorax may be difficult to identify because the free air in the dorsal thorax and the aerated ventral lung appear similar with ultrasound.[28] One also may use ultrasonography prognostically. The detection of free gas echoes (associated with anaerobic bacterial infections or bronchopleural fistulae), extensive fibrinous tags, or areas of loculations within the pleural fluid are associated with a poorer prognosis requiring a more extensive therapeutic regimen.[33]

7.1.5 THORACOCENTESIS

Sampling of the pleural fluid by means of thoracocentesis is beneficial for diagnostic, prognostic, and therapeutic purposes. Abnormal pleural fluid accompanies numerous respiratory disorders, including pulmonary abscessation (pleuropneumonia), chronic pneumonia, systemic mycoses, neoplasia, pulmonary granulomata, and equine infectious anemia. One may perform the technique easily at the sixth or seventh intercostal space approximately 10 cm dorsal to the olecranon by aseptically inserting a teat cannula through an anesthetized site in the intercostal space, just cranial to the border of the rib. To reduce the amount of air aspirated into the pleural cavity, one attaches a three-way stopcock to the cannula. The clinician should take samples from both sides of the thorax and submit the aspirate for cytologic and microbiologic examination. One may obtain up to 100 ml of pleural fluid, although smaller amounts (10 to 30 ml) are more routine.[34] Normal pleural aspirates contain less than 10,000 nucleated cells per µl (60% of which are neutrophils) and less than 2.5 g/dl of protein. Samples should be cultured aerobically and anaerobically. Fluid with a putrid odor is associated with anaerobic bacteria and carries a less favorable prognosis for the horse.[35]

7.1.6 NUCLEAR MEDICINE IMAGING

Scintigraphy, or nuclear medicine imaging, is a specialized technique available at some university and practice facilities. Using γ-emitting radioisotopes such as krypton-81m or technetium-99m, the clinician can assess pulmonary ventilation and perfusion in the horse.[36,37] The horse, breathing through a closed circuit, inhales aerosolized technetium particles generated by a nebulizer. Aerosolized particles are of sufficiently small diameter to be deposited in the alveoli and small airways. Thus their distribution mirrors ventilation. A gamma camera records the sites of deposition within the lung fields. For the perfusion scan, one injects technetium-labeled macroaggregated albumin intravenously. The large protein particles lodge in the blood capillaries of the lung, enabling imaging of the pulmonary perfusion by the gamma camera. Hence lung scintigraphy permits evaluation of the ratio of regional ventilation to perfusion ($\dot{V}$ / $\dot{Q}$) not possible by radiography or ultrasonography. Scintigraphic images may provide additional insights into the diagnosis and pathogenesis of such disorders as chronic obstructive pulmonary disease or exercise-induced pulmonary hemorrhage (EIPH) or 296
in the evaluation of the horse with poor performance.[38,39] For example, horses with EIPH appears to have a 297
perfusion deficit in the caudodorsal lung lobe that results in a high V/Q area.[38] Horses with chronic obstructive pulmonary disease may produce several patterns, including V/Q deficits in the costophrenic angle (caudoventral diaphragmatic margin), ventilation deficits in the middorsal lung area, or patterns similar to those seen in EIPH.

[40] In addition to assessment of pulmonary ventilation and perfusion, scintigraphy can show tracheal mucus transport after intratracheal injection of technetium. One performs the technique by timing the movement of the radioactive bolus over a given tracheal distance.[41,42] Normal values for the unsedated horse range from 16.6 to 20.7 mm/min. Further studies are needed to examine alterations in tracheal mucus transport during disease. For further information, the reader is referred to additional reviews.[40]

7.1.7 PULMONARY FUNCTION TESTING

Measurements of lung volumes, pleural (esophageal) pressure changes, and airflow, coupled with nitrogen washout studies and arterial blood gas determinations, have been used to assess horses with pulmonary disease. Pulmonary function testing requires that the horse wear a breathing apparatus to which an airflow meter has been attached. Pleural pressure changes occurring during each breath are estimated by catheters placed in the midesophagus, exteriorized through the nares, and attached to pressure transducers. By integrating airflow relative to time, one obtains the inspiratory and expiratory volumes. Additional parameters obtained from measurements of airflow include inspiratory and expiratory times, breathing frequency, and peak airflows. In general, the simple measurement of tidal volume, breathing frequency, or minute volume (the product of tidal volume and breathing frequency) provides limited information regarding the functionality of the lung, because these values tend to be maintained near normal limits until the respiratory disease is advanced.[43]

Measures of lung distensibility (dynamic compliance) and airway obstruction (pulmonary resistance) provide more meaningful information regarding pulmonary health. One measures dynamic compliance (C_{dyn}) by dividing the tidal volume by the change in pleural pressure occurring between the start and end of inhalation. One measures pulmonary resistance by several different techniques, depending on whether one measures the resistance at peak airflow or at specific ventilatory volumes (e.g., 50% tidal volume), and calculates it by dividing airflow by the change in pleural (esophageal) pressure. Alterations in these two values can provide information on the nature of the lung disorder. For example, in obstructive disorders of the tracheobronchial tree, dynamic compliance decreases and pulmonary resistance increases. A decrease in dynamic compliance in the absence of a change in pulmonary resistance suggests that the lung parenchyma has been stiffened by alveolar disease or by obstruction of the peripheral bronchioles. (One may recall that peripheral bronchioles, because of their immense cross-sectional area, contribute little to the resistance of breathing until the disorder is well advanced.) Conversely, an increase in pulmonary resistance in the absence of a change in dynamic compliance suggests that the obstruction exists in the upper airway, trachea, or bronchus.[44]

Currently, measures of airway hyperreactivity in horses are becoming more routine at referral centers.[45–47] In this technique, one determines the dosage of a nebulized bronchoconstrictor agent, such as histamine or methacholine, that causes a 35% increase in baseline respiratory resistance or a 35% decrease in baseline lung compliance. As might be predicted, the dosage to achieve this in a horse with inflammatory airway disease or recurrent airway disease is much smaller than that needed to achieve a similar effect in a healthy horse. Measurement of airway hyperreactivity requires that the horse be sedated and outfitted with an airtight breathing mask. Laboratory assistants should wear protective masks to prevent inhalation of the bronchoconstrictor agent.

Pulmonary function testing of *exercising* horses and its use in assessing the poor performer is a new diagnostic approach offered at select referral centers. With the availability of high-speed treadmills and the ability to measure airflow during exercise,[48] analysis of tidal volume, breathing frequency, dynamic compliance, lung resistance, end-expiratory lung volume, and flow-volume and pressure-volume loops may provide additional

insights into the cause of the poor performance, the recognition of expiratory flow limitation, and the documentation of EIPH on respiratory mechanics.

7.1.8

LUNG BIOPSY

A histopathologic diagnosis may prove useful in the therapeutic management of certain lung disorders. Percutaneous lung biopsy has been used to investigate disorders (1) characterized radiographically by a pulmonary miliary pattern and (2) disorders for which radiographic or ultrasonographic results are compatible with pulmonary neoplasia or granuloma.[49] Raphel and Gunson originally described the methodology and application of this technique in equine medicine.[50] The clinician inserts the biopsy instrument aseptically through the seventh or eighth intercostal space, approximately 8 cm above a horizontal line through the scapulohumeral articulation. The technique is not recommended in patients that are tachypneic, are in respiratory distress, exhibit uncontrollable coughing, or have bleeding disorders. The technique is not indicated in cases of 297
pulmonary abscessation, pleuropneumonia, or pneumonia.[49] The most common complications observed with 298
lung biopsy are epistaxis, pulmonary hemorrhage, tachypnea, and respiratory distress. Hemothorax also may develop following lung biopsy.[51]

7.2

Disorders of the Upper Respiratory Tract

One may encounter a variety of disorders of the upper respiratory tract in horses. Presenting complaints for upper airway disorders may include dyspnea (especially inspiratory), nasal discharge, dysphagia, lymphadenopathy, swelling or pain in the throatlatch region, or decreased exercise tolerance. Endoscopic or radiographic examination of the head and upper airway facilitate a diagnosis of most such disorders.

7.2.1

SINUS DISORDERS

7.2.1.1

Sinusitis

7.2.1.1.1

Anatomic Considerations

Six pairs of sinuses communicate with the nasal cavity in the horse: the dorsal, middle, and ventral conchal and the maxillary, frontal, and sphenopalatine.[52] The conchal sinuses, extensions of the turbinates, communicate with the frontal (dorsal conchal) or maxillary sinuses (middle and ventral conchal). However, most clinically important conditions involve the maxillary and frontal sinuses. The sinuses are lined by a respiratory epithelium—pseudostratified ciliated columnar—interspersed with goblet cells and underlying serous glands.[53]

The maxillary sinus is divided into a rostral and caudal compartment by a bony oblique septum. In most horses the division is complete so that no communication exists between the two compartments. Each compartment communicates with the middle nasal meatus by the nasomaxillary opening, a narrow slit that is occluded easily during inflammation of the mucosa. This process leads to retention of exudate within the sinuses. In horses less than 5 years of age, the last three cheek teeth—the first, second, and third molars—occupy most of the maxillary sinus. As the horse ages and the residual root decreases, the sinus cavity enlarges. The larger frontal sinus communicates with the caudal compartment of the maxillary sinus via the

frontomaxillary opening, thus establishing a natural drainage route of the frontal sinus with the nasal cavity. [54]

7.2.1.1.2
Causes

Primary sinusitis or empyema reflects accumulation of exudate within the sinus cavities and is a sequela of viral or bacterial upper respiratory tract infections. Streptococcal (and rarely staphylococcal) organisms are the usual bacterial isolates. Secondary sinusitis (empyema) of the maxillary sinus usually is associated with dental disorders such as fractured teeth, patent infundibula, and alveolar periostitis. The first molar is the most commonly involved tooth. However, secondary sinusitis may follow traumatic head injuries or the development of congenital paranasal cysts. The latter usually are found in the maxillary sinus but also have been identified in the frontal sinus.[55,56] Neoplasms associated with secondary sinusitis include squamous cell carcinoma (most common), osteogenic sarcoma, lymphosarcoma, myxoma, osteoma, sarcoids, neurofibroma, and mast cell tumor.[57,58] Although rare, fungal granulomata induced by *Cryptococcus neoformans* and *Coccidioides immitis* may cause secondary sinusitis.[59,60] Progressive hematomas also may occur in the maxillary sinus.[57]

7.2.1.1.3
Clinical Signs

Clinical signs depend on the inciting agent, its location, and the chronicity of the disorder. A unilateral nasal discharge suggests unilateral sinus involvement; a bilateral nasal exudate suggests that the right and left sinuses are involved. Sinusitis following dental disease or invasive neoplastic masses is characterized by a purulent foul-smelling and persistent nasal discharge, whereas a serosanguineous exudate is more typical of sinus cysts, slowly growing neoplasms, and certain stages of mycotic granulomata and hematomas. Inflammatory reactions of the skin, subcutaneous tissues, teeth, and bones may produce facial asymmetry. When sinus inflammation extends into the periorbital region, exophthalmos may ensue. Other clinical signs associated with sinusitis include breathing difficulties, epistaxis, epiphora, headshaking, weight loss, and neurologic signs if the sinusitis extends through the cribriform plate and causes meningoencephalitis.

7.2.1.1.4
Diagnosis

Diagnosis is based on the history of the disorder, the age of the animal, and the nature of the clinical signs. Percussion of the sinuses may reveal dullness. Endoscopic examination helps to eliminate other potential sources of nasal discharge and demonstrates the presence of an exudate from the nasomaxillary opening, visualized from the middle meatus just proximal to the ethmoids. This visualization confirms that the exudate originates from the sinus compartment. One may further define the sinus disorder by sinuscopy or computed tomography scan. The clinician always should conduct a thorough oral examination of the upper dental arcade even if it requires short-acting anesthesia. The presence of fractured or displaced teeth, receding gum lines, exudate around a specific tooth, or patent infundibula suggests that dental disease is the cause of the disorder. Lateral and dorsoventral radiographs are helpful in diagnosing sinusitis and may demonstrate single or multiple horizontal fluid-air interfaces, abnormalities of the teeth, lysis of alveolar bone, or a combination of these (Figures 7-6 and 7-7). Nuclear scintigraphy may indicate increased uptake of radioisotope around an infected tooth root.[61] Neoplastic lesions may be visible radiographically as loculated or diffuse soft tissue densities. Culture and cytologic examination of the sinus fluid or biopsy of 298
the tissue mass is helpful in the diagnosis, although differentiating between a neoplastic or dysplastic 299

process or inflammatory reaction may be difficult. Tumors may vary in consistency but usually have gelatinous areas mixed with combinations of cysts and solid tissue (fibrous tissue).[62]

7.2.1.1.5

Treatment

Treatment requires surgical removal of the affected teeth or tumorous or granulomatous tissue and establishment of adequate drainage. Extensive flushing of the sinuses has been recommended until the trephine sites have healed. Surgical removal of paranasal cysts has been associated with a favorable prognosis,[56] whereas fungal granulomata and neoplasms have a poor prognosis. With neoplastic lesions, surgical resection or ablation apparently achieves a low rate of success because of extensive infiltration of the neoplasm or recurrence of the tumor.[58,62]

7.2.1.2
Ethmoid Hematomas

7.2.1.2.1
Definition

Ethmoid hematomas are encapsulated, expansive angiomatous masses that appear to develop from the mucosal lining of the ethmoid conchae but also may originate from the walls of the maxillary and frontal sinus. The inciting factor in their development is not known. Some have speculated that ethmoid hematomas develop following chronic infection, repeated episodes of hemorrhage, or congenital or neoplastic conditions.[63] They appear bilaterally in 50% of the cases and are more prevalent in older horses.[64]

7.2.1.2.2
Clinical Signs

Clinical signs include intermittent unilateral discharge consisting of frank blood or serous or mucopurulent exudates. Stertorous breathing because of obstruction of nasal air flow also may occur.[63] Clinical signs also may include facial swelling, exophthalmos, malodorous breath, headshaking, and coughing.[59] 299

300

7.2.1.2.3
Diagnosis

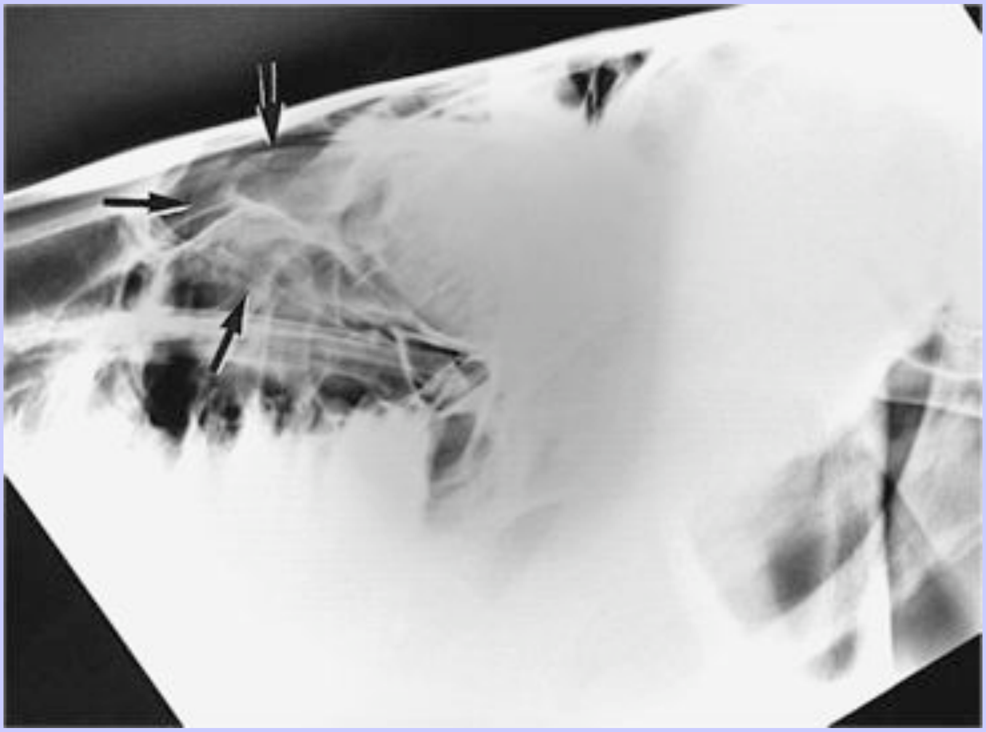
Diagnosis is based on the clinical signs, endoscopic examination, radiographic evaluation, and in some cases computed tomography scan. Confirmation of a diagnosis is by histopathologic study of the removed tissue. Endoscopy (see Figure 7-2) reveals a yellow, yellow-green, yellow-gray, red to red-purple smooth glistening mass originating from the ethmoid region.[63] One also may note petechial hemorrhages or surface erosions. The mass may protrude beyond the nasal septum (and in those cases may cause a bilateral nasal discharge). Radiographs reveal a space-occupying soft tissue density with smooth margins. Single or multilobular rounded opacities may be visible radiographically in the ventral aspect of the caudal maxillary sinus superimposed on the ethmoid turbinates. The ethmoid hematoma in some cases may extend dorsally into the frontal sinus (Figure 7-8).

7.2.1.2.4
Treatment

Treatment options include surgical resection, cryosurgery, laser ablation, and formalin injection. Surgical removal is associated with extensive hemorrhage, and surgery may require blood transfusions. A preoperative crossmatch is warranted, and the horse may require a postoperative tracheotomy if one uses extensive packing of the nasal cavity to effect hemostasis. Antimicrobials and antiinflammatory agents are indicated. Following surgical removal, approximately 20% to 50% of the hematomas recur.[63,64] Postoperative complications may include facial wound dehiscence, suture periostitis, facial bone sequestration, persistent nasal discharges, fungal sinus plaque formation, and encephalitis.[65]

Transendoscopic injection of lesions with formalin is an alternative to surgical resection, particularly for smaller lesions. Most cases require multiple injections.[66] Severe complications also may ensue if the cribriform plate is fenestrated, allowing communication of the ethmoidal hematoma with the cranial vault.[67]

Figure 7-8 Ethmoidal hematoma. Focal increased soft issue opacity *(arrows)* adjacent to the ethmoids is notable. (Courtesy D.S. Biller, Manhatten, Kansas, 1991.)



7.2.2 GUTTURAL POUCH DISORDERS

7.2.2.1 Anatomic Considerations

The guttural pouches are caudoventral diverticula of the auditory tubes the functions of which remain undefined, although some investigators have suggested that the pouches play a role in cooling the arterial supply to the brain.[68] Each pouch has a capacity of 300 ml and is divided into a medial and lateral compartment by the invagination of the stylohyoid bone. The mucosal lining of each pouch is secretory, being covered by ciliated pseudostratified epithelium with goblet cells and glands.[69] The mucosal lining is generally thinner than that found in the nasopharynx and also contains small aggregates of subepithelial lymphocytic tissue.[53]

Disorders of the guttural pouches often induce dysfunctions of the surrounding neural structures—cranial nerves VII, IX, X, XI, and XII and the sympathetic trunk, or cause erosion of the vascular structures—the internal carotid, the external carotid, and the maxillary arteries.

7.2.2.2 Tympany

7.2.2.2.1 Definition

Tympany is a nonpainful distention of the guttural pouch by air that may produce an external swelling in the parotid region. Congenital tympany occurs in young foals (predominantly fillies), and acquired tympany usually affects older horses.[70]

7.2.2.2.2 Pathogenesis

The cause of congenital guttural pouch tympany is unknown. An abnormal mucosal flap at the pharyngeal orifice has been proposed to function as a unidirectional valve, trapping air or fluid within the pouch. Tympany is more likely a functional defect rather than an anatomic defect because no abnormality is visible endoscopically or during surgical exploration. Acquired tympany typically is associated with upper respiratory infection and is thought to be caused by swelling of tissues around the pharyngeal orifice, causing a one-way valve effect. This problem is transient, and rarely does pouch distention become severe.

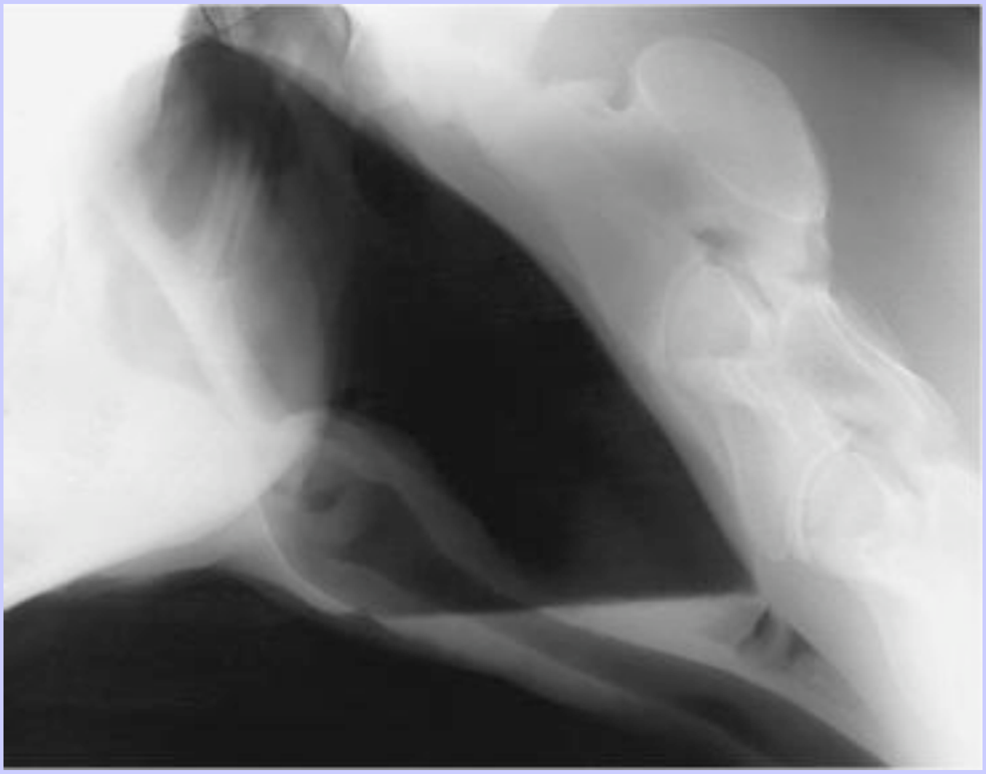
7.2.2.2.3 Clinical Signs

Clinical signs depend on the degree of pouch distention and hence the degree of compression of the nasopharynx. If distention is significant, the foal may exhibit stertorous breathing, respiratory distress, dysphagia, nasal discharge, or evidence of pneumonia caused by aspiration. Regurgitation of milk from the nostrils also may be evident.[71] Endoscopic examination may reveal significant compression of the nasopharyngeal area because of distention of the pouches.

7.2.2.2.4 Diagnosis

Confirmation of diagnosis is by the presence of tympanitic swelling in the Viborg's pouch area.
Radiographs reveal a large, air-filled guttural pouch with or without fluid accumulation (Figure 7-9). The 300
distinction as to whether the problem is unilateral or bilateral can be difficult. Catheterization of one 301
guttural pouch should correct the problem if a unilateral tympany exists. Dorsoventral radiographic views may help in diagnosing bilateral involvement.

Figure 7-9 Guttural pouch tympany. Lateral radiograph of 5-month-old Arabian colt demonstrating a greatly distended gas-filled pouch. (Courtesy D.S. Biller, Manhatten, Kansas, 1991.)



7.2.2.2.5
Treatment

Guttural pouch tympany requires surgical correction. For unilateral tympany, one performs fenestration of the median septum separating the two guttural pouches by conventional surgery or transendoscopic laser surgery. Bilateral involvement may necessitate resection of the excessive plica salpingopharyngeal flap.[72] Because many cultures of the pouches yield β-hemolytic streptococci and the potential for the development of aspiration pneumonia exists, administration of antimicrobials is justified.[70] The prognosis for uncomplicated cases of guttural pouch tympany is favorable.

7.2.2.3
Empyema

7.2.2.3.1
Definition

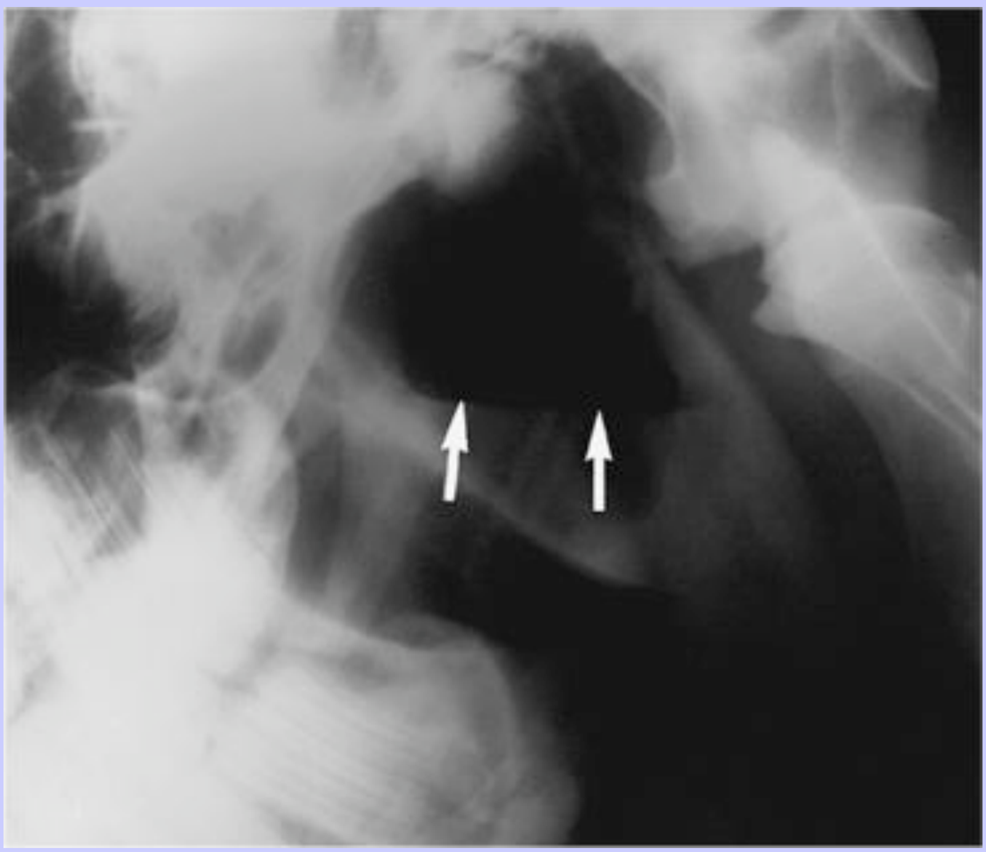
Empyema is an accumulation of exudate within the guttural pouches and is usually a sequela of upper respiratory tract infections (*Streptococcal* spp.). In a recent survey, *Streptococcus equi* was isolated from 32% of the cases evaluated for empyema.[73] Empyema may also result from the rupture of abscessed

retropharyngeal lymph nodes into the pouches[71] or may accompany cases of guttural pouch tympany. The condition may be unilateral or bilateral.

7.2.2.3.2 Clinical Signs

Clinical signs include a white nonodorous nasal discharge (unilateral or bilateral), lymphadenopathy, painful distention in the parotid region, stertorous breathing, dysphagia, and occasionally epistaxis.[71] Inspissation of the material may occur with chronic infections, forming masses called chondroids.

Figure 7-10 Guttural pouch empyema. Lateral radiograph shows a fluid line *(arrows)* or air-fluid interface within the guttural pouch. (Courtesy D.S. Biller, Manhatten, Kansas, 1991.)

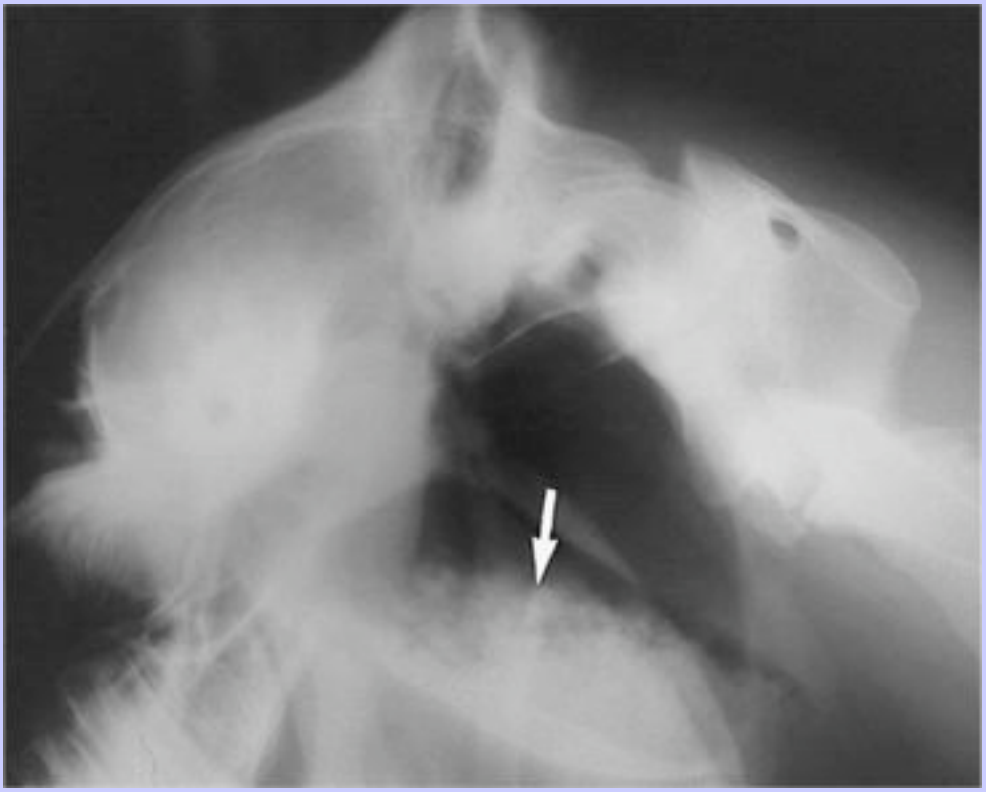


7.2.2.3.3 Diagnosis

Confirmation of diagnosis is by radiographic examination or endoscopy. Radiographs demonstrate a fluid line or an opacity in the pouch (Figure 7-10). Inspissated material also may be evident radiographically 301
(Figure 7-11). Endoscopic examination may reveal a purulent material at the pharyngeal orifice of the 302
auditory tubes and within the medial or lateral compartments of the guttural pouches. Small pebblelike

structures, chondroids, also may be visible endoscopically. Distortion of the pharynx may occur if distention is significant.

Figure 7-11 Guttural pouch chondroids. Lateral radiograph demonstrates irregular soft tissue opacities in the ventral guttural pouch outlined by gas *(arrow)*. (Courtesy D.S. Biller, Manhatten, Kansas, 1991.)



7.2.2.3.4

Treatment

Because *S. equi* may be involved, the clinician should isolate affected horses and take precautions to avoid spread of the bacteria (see the following discussion). Treatment may entail medical and surgical modalities. Aggressive lavage of the guttural pouch with saline solutions and the administration of systemic antimicrobials is a first step in therapeutic management.[73] One may attempt removal of chondoids with an endoscopic snare, avoiding the complications or risk of surgery and minimizing the cost of treatment.[74] Surgery may be necessary if medical therapy is unsuccessful.[71]

7.2.2.4
Mycosis

7.2.2.4.1
Definition

Guttural pouch mycosis is characterized by development of fungal plaques on the mucosal walls of the guttural pouches. The plaques usually are found at two sites, with the majority of them located on the roof of the medial compartment and less frequently on the lateral wall of the lateral compartment of the pouch. The plaques are associated closely with the underlying vascular structures, the internal and external carotid arteries, or the external maxillary artery.[75]

7.2.2.4.2
Pathogenesis

The events leading to the formation of fungal plaques are not known. Some workers have suggested that aneurysmal dilations of the vasculature, visualized radiographically,[76] provide a suitable environment for fungal organisms to proliferate. Fungal colonization leads to erosion of the underlying mucosa and vascular structures or inflammatory injury to the adjacent nerves.

7.2.2.4.3
Clinical Signs

Clinical signs depend on the integrity of the neural and vascular structures surrounding the guttural pouch. Horses may exhibit episodes of spontaneous epistaxis, dysphagia, nasal catarrh, laryngeal hemiplegia, Horner's syndrome, abnormal head extension, swelling in the parotid region, facial paralysis, mycotic encephalitis, and atlantooccipital joint infections.[77] The stress of being handled may precipitate fatal epistaxis in the horse.

Although guttural pouch mycosis is uncommon in the young horse, it has been reported in foals less than 6 months of age.[78,79]

7.2.2.4.4
Diagnosis

Confirmation of diagnosis is by endoscopic observation of a fungal plaque in the guttural pouch. Shortly after an acute bout of epistaxis, endoscopic examination can confirm that blood is exiting the pouch, but attempts to visualize the interior of the pouch may be unsuccessful if blood obscures the visual field of the endoscope. Some risk exists of dislodging a blood clot if one performs endoscopic examination of the pouch.[75] Endoscopic confirmation of secondary neuropathies such as pharyngeal paralysis or laryngeal hemiplegia supports the diagnosis of guttural pouch mycoses.

Radiographs of the guttural pouch may show evidence of fluid accumulation or osteolytic changes in the stylohyoid bone or may suggest mycotic plaque formation. Angiographic demonstration of aneurysms of the internal or external carotid artery supports the diagnosis and may aid in surgical planning.

7.2.2.4.5

Treatment

Treatment depends on surgical occlusion of the affected vessels. Several different techniques have been advocated.[75,80–83] Current therapies of choice use an intravascular balloon or coil to allow obliteration of arterial flow proximal and distal to the fungal lesion. Complications, including ischemic optic neuropathy and those associated with aberrant vasculature, have been reported.[84,85] Lane[75] has recommended that surgical treatment be combined with topical therapy (natamycin irrigation of the guttural pouch) and supportive care. Horses that have dysphagia may need enteral support via nasogastric intubation or esophagostomy. Medical treatment alone, with topical or parenteral antimycotic drugs, is not efficacious in eliminating the mycotic plaques.

7.2.3

PHARYNGEAL AND LARYNGEAL DISORDERS

7.2.3.1

Lymphoid Hyperplasia

7.2.3.1.1

Definition

Acute inflammation of the lymphoid (and surrounding) tissues in the pharynx is termed *pharyngitis*. The condition occurs with equine influenza, EHV1, EHV2, and EHV4 and with *Streptococcus equi* infections. Acute pharyngitis also may develop with prolonged nasogastric intubation. Chronic inflammation of the pharynx, also termed *pharyngeal lymphoid hyperplasia, lymphoid follicular hyperplasia,* and *pharyngeal folliculitis,* is a condition frequently observed in weanlings to performance horses 2 to 3 years of age.[86]

7.2.3.1.2

Causes

The cause of chronic pharyngitis is not known but probably is multifactorial. Many horses have a history of upper respiratory tract infections, causing some clinicians to speculate that lymphoid hyperplasia is a sequela of chronic antigenic stimulation. The condition has been reproduced experimentally with inoculation of EHV1 and EHV2.[87,88] The severity of the pharyngeal lymphoid hyperplasia does not correlate with EHV1 titers or with the isolation of EHV2.[89]

Streptococcus zooepidemicus, Bordetella bronchiseptica, and *Moraxella* species have been isolated from nasopharyngeal swabs of horses with lymphoid hyperplasia, but their role in the development of the lymphoid hyperplasia is also unknown. In one study the pharyngeal flora was similar in normal control horses and in those exhibiting grade I lymphoid hyperplasia. As the severity of the pharyngitis increased, the number of bacterial organisms that were isolated (colony-forming units per gram of swab material) also increased.[90] 302

303

7.2.3.1.2.1

BOX 7-2 GRADING SCHEME FOR LYMPHOID HYPERPLASIA

Grade I: A small number of inactive, white follicles scattered over the dorsal pharyngeal wall. The follicles are small and inactive, a normal finding in horses of all ages.

Grade II: Many small, white inactive follicles over the dorsal and lateral walls of the pharynx to the level of the guttural pouch. Numerous follicles that are larger, pink, and edematous are interspersed throughout.

Grade III: Many large pink follicles and some shrunken white follicles are distributed over the dorsal and lateral walls of the pharynx, in some cases extending onto the dorsal surface of the soft palate and into the pharyngeal diverticula.

Grade IV: More numerous pink and edematous follicles packed close together covering the entire pharynx, the dorsal surface of the soft palate and epiglottis, and the lining of the guttural pouches. Large accumulations appear as polyps.

From Raker CW: The nasopharynx. In Mansmann RA, McAllister ES, editors: *Equine medicine and surgery,* Santa Barbara, Calif, 1982, Veterinary Publications.

The contribution of husbandry factors to the development or maintenance of lymphoid hyperplasia also has been examined. Young horses that are stabled indoors have a more severe pharyngitis than when kept outdoors with access to a three-sided shelter.[91]

7.2.3.1.3 Epidemiology

An inverse relationship appears to exist between the age of the horse and the prevalence of pharyngeal lymphoid hyperplasia. Approximately 60% to 90% of 2-year-olds exhibit a grade II or more (Box 7-2). Between 35% and 65% of 3- and 4-year-olds and 10% to 20% of 5-year-olds still show grade II or greater lymphoid hyperplasia. With aging, lymphoid follicles regress and tend to disappear.

7.2.3.1.4 Clinical Signs

Some horses may show a nasal discharge and mild submandibular lymphadenopathy. Manipulation of the larynx may induce a cough. Unless severe, lymphoid hyperplasia has not been associated with poor performance or alterations in arterial blood gases.[92]

7.2.3.1.5 Diagnosis

Endoscopically, one observes raised hyperemic and edematous follicles distributed throughout the nasopharyngeal walls. Some follicles may have an ulcerated edge to them; others may appear thickened and fibrotic. Raker[93] proposed a gradation scheme based on the severity of the nodule formation, as outlined in Box 7-2. Histopathologic examination reveals lymphocytic proliferation and necrosis, the degree of which does not correlate with endoscopic findings.

7.2.3.1.6 Treatment

In the absence of a clear understanding of the pathogenesis of this disorder, the most appropriate therapy has not been determined. One treatment that has been tried is nebulization (30 min/day) using an antiinflammatory solution (350 ml nitrofurazone, 125 ml dimethyl sulfoxide, and 500 mg prednisolone acetate). Stabling changes to reduce dust and mold exposure may be helpful.

7.2.3.2 Dorsal Displacement of the Soft Palate

7.2.3.2.1 Definition

During respiration, the caudal free border of the soft palate normally occupies a position ventral to the epiglottis. This position reverses abruptly during swallowing as the palate moves dorsally and the epiglottis covers the adducted arytenoid cartilages and vocal folds. These motor activities ensure that food or saliva is directed dorsally into the esophagus and not into the trachea.[94] The positioning of the palate is complex, controlled in part by the palatine, the tensor, and the levator muscles, which are innervated by the trigeminal, vagus, and glossopharyngeal nerves, respectively. Intermittent or persistent malpositioning of the soft palate dorsal to the epiglottis is termed *dorsal displacement of the soft palate* (DDSP).[95]

7.2.3.2.2 Causes

On occasion, persistent displacement is evident endoscopically at rest. This finding may be associated with pharyngeal paralysis of numerous causes, but in the absence of signs of dysphagia, the condition often is caused by mechanical or inflammatory mechanisms that obliterate the subepiglottic space (subepiglottic cyst, epiglottitis, epiglottic entrapment, subepiglottic fibrosis, etc.). In most cases of DDSP, palate position is normal on resting and displacement occurs only during strenuous exercise. The cause of displacement in such cases is unclear. Formerly suggested mechanisms including excessively negative intrapharyngeal pressures,[96] excessive poll flexion,[97] epiglottic shortening,[98] and caudal retraction of the larynx by the sternothyrohyoideus[94] now appear largely unfounded. Recent studies have focused on palatal innervation and on factors controlling the relative positions of the larynx and hyoid apparatus as potential causes of palate displacement. Bilateral blockade of the pharyngeal branch of the vagus nerve with local anesthetic has been shown to cause DDSP, implicating a dysfunction of the palate musculature or its innervation as the cause.[99] Furthermore, the observation that some horses with displacement have lymphadenopathy of retropharyngeal nodes that lie in close proximity to the pharyngeal nerves supports the hypothesis that a neuropathy is contributory.[100] Other investigators have evaluated the effects of altering the relationships between the larynx and hyoid apparatus through denervation or transection of various muscles inserting on 303
those structures. Selective transection of the thyrohyoideus muscle causes intermittent dorsal displacement 304
of the palate in some horses, leading to speculation that neuromuscular disorders of this muscle may predispose to displacement.[101] Recent observations that DDSP and nasopharyngeal collapse were observed in horses following desensitization of the laryngeal mucosa with local anesthetic suggests that receptors within the laryngeal mucosa may be important in maintaining upper airway patency in exercising horses.[102]

7.2.3.2.3 Pathogenesis

Along with dorsal displacement of the soft palate is a reduction in the cross-sectional area of the nasopharynx. This increases the resistance to airflow and may occlude the passageway completely, temporarily inducing asphyxia (choking down). The displacement creates a stertorous noise most obvious during expiration as the soft tissues vibrate. Because of the obstruction, airflow may be diverted through the mouth during expiration. A study of 10 horses exercising on a high-speed treadmill found that the time of displacement relative to exercise intensity varied, occurring in two horses at peak speed, in two horses before obtaining peak speed, and in six horses as they started to slow down during the exercise protocol.[96]

The time of displacement relative to the breathing-swallowing cycle also varied, with displacement occurring during inspiration in three horses, during expiration in three horses, and being associated with a swallow in four horses.[96]

7.2.3.2.4

Clinical Signs

The cardinal signs of DDSP are respiratory noise and decreased exercise tolerance. Signs are often dramatic, leading to the descriptor “choking down.” Affected horses typically make an inspiratory and expiratory noise, but the latter is much more prominent. The noise often is described as snoring, rattling, or gurgling. Occasionally, a horse may show an expiratory noise at rest or while eating. Clinical signs are ordinarily apparent only during strenuous exercise. In racehorses, a history of acute onset of noise and respiratory embarrassment is frequent. Normal respiratory function returns immediately when the horse swallows.

7.2.3.2.5

Diagnosis

Given the intermittent nature of the displacement, diagnosis is often difficult to confirm. Definitive diagnosis is by observation of displacement during endoscopic examination while the horse is exercising rigorously on a high-speed treadmill. With displacement the caudal border of the palate moves dorsal to the epiglottis, obscuring its shape. The caudal free border of the palate is evident, as is dorsal billowing of the palate on expiration. Before the actual displacement, a lowering of the pharyngeal roof, an elevation of the rostral portion of the soft palate, and a caudal retraction of the larynx are apparent.

In the absence of treadmill access, diagnosis is based subjectively on typical historical findings and resting endoscopic examination. An important note is that most horses examined at rest have no evidence of DDSP.This examination primarily enables the clinician to rule out other causes of upper respiratory obstruction. In some horses, endoscopic findings such as ready displacement by nasal occlusion, ulceration of the free border of the soft palate, or epiglottic hypoplasia or deformity may support a diagnosis of DDSP. Normal horses often exhibit palate displacement during resting endoscopy, especially if sedated, excessively restrained, or subjected to tracheoscopy.

Radiographs of the larynx may demonstrate a hypoplastic epiglottis, that is, one less than 7 cm in length. The clinician should perform a thorough examination of the lower respiratory tract (e.g., auscultation and endoscopy) on these horses to rule out concomitant pulmonary disease.

7.2.3.2.6

Treatment

Treatment varies and includes medical and surgical approaches. Medical therapy includes tying the tongue, use of a cavesson or figure-eight noseband to keep the mouth closed and treatment of concurrent upper respiratory disorders. One uses the tongue tie in an attempt to prevent caudal retraction of the larynx and subsequent displacement of the soft palate. Keeping the mouth closed is thought to protect the laryngopalatal seal. A short course of nebulization therapy using a solution of 350 ml of liquid nitrofurazone (Furacin), 125 ml of dimethyl sulfoxide, and 500 mg of prednisolone acetate (30 min/day for 7 to 10 days) may be helpful in horses with guttural pouch or pharyngeal inflammation.

The variety of surgical options for treating DDSP reflects the limited understanding of the cause of this disease. Described surgical treatments include resection of the caudal margin of the soft palate

(staphylectomy) to increase the size of the ostium intrapharyngeum,[95] partial sternothyrohyoideus myectomy to prevent caudal retraction of the larynx, and epiglottic augmentation by injection of Teflon into the epiglottal submucosa.[103] The current procedure of choice in North America is a combination of conservative staphylectomy and resection of the musculotendinous junction of sternothyroideus muscle, the Llewellyn procedure.[104] Dorsal displacement of the soft palate is a difficult condition to treat: the success rate for the myectomy and staphylectomy approaches 50% to 60%.[105]

7.2.3.3 Rostral Displacement of the Palatopharyngeal Arch

7.2.3.3.1 Definition

In the horse the soft palate terminates caudally by the confluence of the caudal pillars to form the palatopharyngeal arch that covers the esophageal orifice.[95] In rostral displacement of the palatopharyngeal arch, this fold of tissue appears to be displaced forward, overlying the apices of the arytenoid cartilages. Cook[106] first described the condition in 1974; others have diagnosed the condition since that time. 304

305

7.2.3.3.2 Causes

The displacement of the palatopharyngeal arch is associated with malformation of the thyroid cartilage and the cricopharyngeal and cricothyroid muscles. Goulden, Anderson, Davies, et al.[107] have speculated that the anomaly results from developmental defects of the fourth branchial arch, which normally forms the thyroid cartilage.

7.2.3.3.3 Pathogenesis

Cartilaginous and muscular defects have been found in this condition. A deformation of the thyroid cartilage, a lack of the cricothyroid articulation, and often an absence or agenesis of the cricothyroid and cricopharyngeal muscles occur.[107,108] Abnormal pharyngeal configurations prevent normal deglutition, predisposing horses to develop aspiration pneumonia.

7.2.3.3.4 Clinical Signs

The condition may be present from birth. In most cases, abnormal respiratory noise and poor athletic performance are the presenting complaints. In severe cases, horses may exhibit dysphagia, nasal discharge of food material, persistent coughing, and belching.[106,107]

7.2.3.3.5 Diagnosis

The diagnosis is based on the clinical signs and history confirmed with endoscopic examination. The rostrally displaced palatopharyngeal arch obscures the normal view of the apices of the arytenoid cartilages. Postmortem examination or surgical exploration of the larynx confirms the presence of developmental defects.

7.2.3.3.6

Treatment

Rostral displacement of the palatopharyngeal arch is an endoscopic sign representing a major deformation of the laryngeal structures. Resection of the arch by conventional surgery or laser surgery has not enabled successful athletic performance.[109] Severely affected horses are euthanized.

7.2.3.4

Epiglottic Entrapment

7.2.3.4.1

Definition

The aryepiglottic fold is the mucous membrane that extends from the lateral aspect of the arytenoid cartilages to the ventrolateral aspect of the epiglottis, where it blends with the subepiglottic mucosa and the glossoepiglottic fold. In epiglottic entrapment, this membrane envelops a portion of or all of the epiglottis.[95,110]

7.2.3.4.2

Causes

The cause of epiglottic entrapment is not understood completely. In most cases, the epiglottic cartilage and associated soft tissues appear normal. In occasional cases, congenital epiglottic hypoplasia or inflammation of the upper respiratory tract structures appears to contribute to entrapment.

7.2.3.4.3

Epidemiology

Epiglottic entrapment occurs predominantly in Standardbred and Thoroughbred racehorses, with males and females equally affected.[111]

7.2.3.4.4

Pathogenesis

Billowing of the entrapping membranes during respiration decreases the cross-sectional area of the pharynx and effectively obstructs the airflow, particularly during expiration.

7.2.3.4.5

Clinical Signs

Most horses show exercise intolerance and respiratory stertor. Horses occasionally may cough during exercise or while eating. Because entrapment may be an intermittent finding, one should confirm the persistence of the entrapment during exercise by endoscopic examination during exercise or immediately following completion of exercise.

7.2.3.4.6

Diagnosis

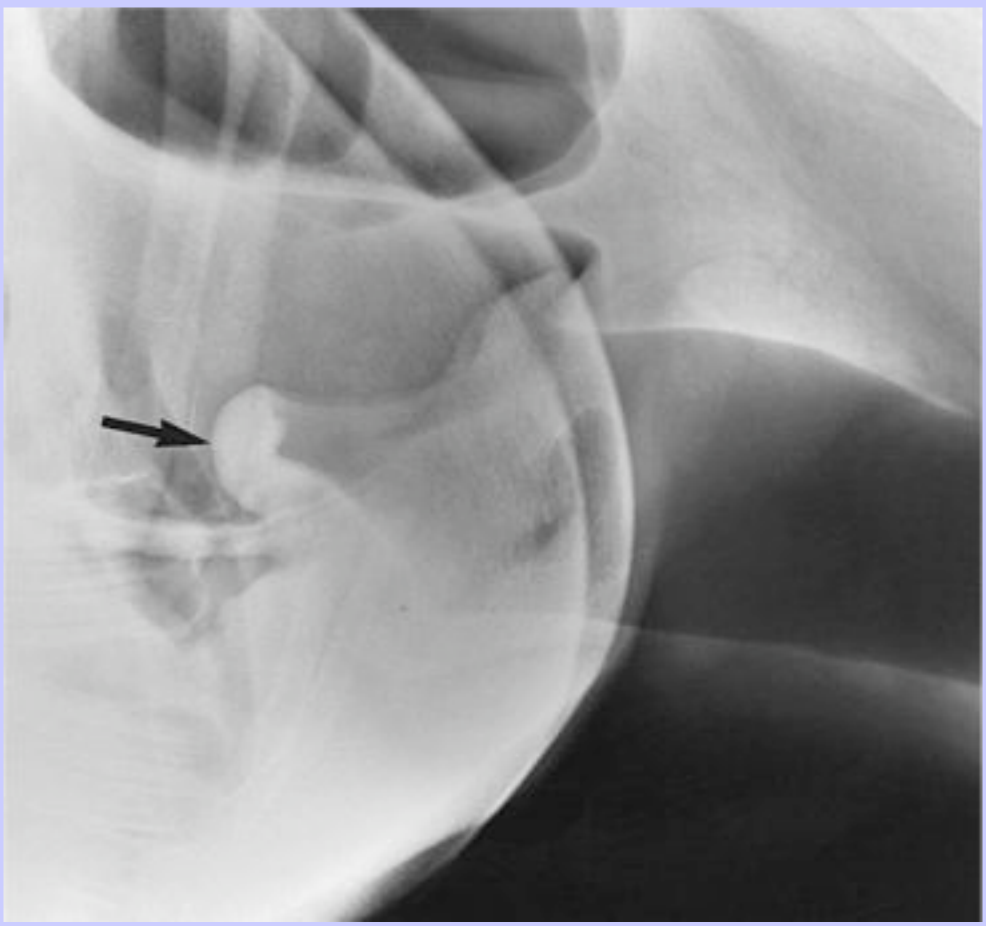
Diagnosis is based on endoscopic examination. The membrane obscures the normal serrated margin of the epiglottis and its dorsal vasculature. In contrast to dorsal displacement of the soft palate, one still can appreciate the shape of the epiglottis. Ulceration of the free margin of the fold and erosion of the entrapped

epiglottis may be apparent.[95] Epiglottic length may be determined radiographically.[98] One also may visualize the entrapment on lateral radiographs (Figure 7-12).

7.2.3.4.7
Treatment

Entrapment requires surgical correction. A number of different approaches have been advocated. One may accomplish resection or division of the tissue (1) under general anesthesia via pharyngotomy, laryngotomy, or by an oral approach; (2) transendoscopically, using a contact Nd:YAG laser; or (3) transnasally, using a hooked bistoury.[111,112] Augmentation of the hypoplastic epiglottis by Teflon submucosal injections has been advocated to increase the bulk of the epiglottis and thus offset some of the structural defects that may predispose to entrapment.[103] One performs this procedure through a ventral laryngotomy.

Figure 7-12 Seven-year-old male Standardbred with an entrapped epiglottis. Lateral radiograph of the larynx demonstrates a rounded distal end to the epiglottis *(arrow)*. The epiglottis also appears shortened. (Courtesy D.S. Biller, Manhatten, Kansas, 1991.)



306

7.2.3.5 Epiglottitis

7.2.3.5.1 Definition

Epiglottis is an acute inflammatory disorder affecting the epiglottis.

7.2.3.5.2 Causes

The cause of epiglottitis is unknown. Racehorses in active training are affected most commonly. Suggested causes include respiratory tract infection, allergens, palate displacement, epiglottic entrapment, inhaled foreign material, poor quality hay, and the stress of race training.[113]

7.2.3.5.3 Clinical Signs

Primary clinical signs include exercise intolerance, respiratory noise, and coughing. Dysphagia and respiratory distress are less common signs.

7.2.3.5.4 Diagnosis

Diagnosis is by endoscopic examination. Signs include epiglottic thickening and ulceration, edema and discoloration of the epiglottic mucosa and aryepiglottic folds, and dorsal elevation of the epiglottic axis. Ulceration may expose the cartilage at the tip of the epiglottis or may be evident as granulation tissue on the underside of the epiglottis. Dorsal displacement of the soft palate is a frequent accompanying finding and may obscure visualization of the epiglottis. In such cases, lateral pharyngeal radiographic or transoral endoscopic evaluation of the epiglottis is of diagnostic value. Epiglottitis frequently is misdiagnosed as epiglottic entrapment on endoscopy.

7.2.3.5.5 Treatment

Treatment is conservative, consisting of stall rest, systemic antiinflammatory drugs, and topical treatment with antiinflammatory drugs and antibiotics. Most horses respond satisfactorily to treatment, but some occasionally require surgical resection of fibrotic or abscessed subepiglottic tissues. Long-term complications include epiglottic deformity, intermittent or persistent palate displacement, and epiglottic entrapment.

7.2.3.6 Pharyngeal Cysts

7.2.3.6.1 Definition

Pharyngeal cysts are fluid-filled structures that have been found in the subepiglottic tissues, in the dorsal nasopharynx, and within the soft palate.[114,115] Depending on their location, the cysts may represent embryonic remnants of the thyroglossal and craniopharyngeal ducts. The cysts usually are considered congenital. Acquired cysts are associated with secretory cells and may occur following obstruction or

inflammation of the mucous glands.[95,115] Pseudostratified cuboidal or columnar epithelium or squamous epithelium usually line the cysts, which often contain thick, yellow mucus.

7.2.3.6.2 Clinical Signs

A foal affected with a large pharyngeal cyst may exhibit signs of respiratory obstruction or dysphagia in the immediate postnatal period. Cough, nasal discharge, nasal milk reflux, and signs of pneumonia may be evidence of accompanying aspiration pneumonia. More typically, the affected horse is asymptomatic until rigorous training begins and signs of abnormal respiratory noise and exercise intolerance become evident. Horses may cough occasionally as well. Dorsal displacement of the soft palate may coexist.

7.2.3.6.3 Diagnosis

Confirmation of diagnosis is by visualization of smooth-walled structures 1 to 5 cm in diameter. Subepiglottic cysts may distort the appearance of the epiglottis, causing it to assume a more upright position in the pharynx. Endoscopic differentiation between subepiglottic and soft palatal cysts may be difficult. Lateral radiographs of the pharynx and larynx or transoral endoscopic examination of the epiglottis may be useful in distinguishing cysts from conformational defects of the epiglottis.

7.2.3.6.4 Treatment

Treatment is surgical resection of the cyst via a ventral midline laryngotomy. Some cysts may be accessible via Nd:YAG laser techniques, eliminating the need for general anesthesia. Broad-spectrum antimicrobials are indicated because of the potential for development of aspiration pneumonia, and the clinician should initiate therapy immediately. A course of 7 to 10 days may be indicated postoperatively, depending on the involvement of the lower respiratory tract structures.

7.2.3.7 Arytenoid Chondritis

7.2.3.7.1 Definition

Arytenoid chondritis is an abnormal enlargement of the arytenoid cartilages associated with chronic inflammation.[116]

7.2.3.7.2 Epidemiology

The condition is primarily a disease of horses performing at high speeds. Although the racing Thoroughbred or Standardbred primarily is affected, the condition has been described in other breeds.[117]

7.2.3.7.3 Pathogenesis

The cause of arytenoid chondritis is unknown, but trauma, inflammation, and infection have been cited as potential causes. In most cases the onset of clinical signs is insidious and progressive, but occasionally, arytenoid chondritis may follow an acute episode of laryngeal infection. Histopathologic findings in this condition are consistent with a chronic recurrent inflammatory process. Involved cartilage is greatly

thickened and laminated with fibrous connective tissue. Intralumenal granulomata and sinus tracts are observable in some cases. Airway obstruction is caused by physical enlargement of the affected arytenoid cartilage and axial movement of the cartilage as it enlarges. The condition is typically unilateral, though often secondary contact damage ("kissing lesion") occurs to the contralateral cartilage. In most cases the condition is progressive and debilitating, and thus the clinician should give a guarded to poor prognosis.[115]

7.2.3.7.4 Clinical Signs

Clinical signs include exercise intolerance and inspiratory stridor during exercise. In some horses one easily can elicit a cough with tracheal compression. Palpation of the larynx suggests that the cartilages are less resilient than normal.[118] In severe cases of chondritis, dyspnea at rest may be evident.

7.2.3.7.5 Diagnosis

Diagnosis is based on endoscopic examination. Mildly affected horses retain arytenoid mobility yet have 306
ulcerations of the body of the affected cartilage or granulomata that project into the laryngeal lumen. In 307
more advanced cases, the affected arytenoid cartilage is immobile and deviated axially. Such cases may mimic laryngeal hemiplegia, but most have additional findings of ulceration, granuloma, deformity of the corniculate process, or a kissing lesion on the contralateral cartilage.[117] Other abnormalities, such as aryepiglottic entrapment or dorsal displacement of the soft palate, may be evident. Radiographs may reveal excessive mineralization of laryngeal cartilages.

7.2.3.7.6 Treatment

Treatment includes medical and surgical approaches. Rest, nonsteroidal antiinflammatory therapy, antimicrobials, and throat sprays or nebulization may be helpful in some cases.[117] In horses that retain arytenoid mobility yet have an intralumenal granuloma, transendoscopic laser debulking is indicated. More advanced cases require surgical resection of the affected cartilage. Several techniques have been advocated. Arytenoidectomy involves removal of the corniculate and arytenoid cartilages, including the muscular process. Partial arytenoidectomy (with ventriculectomy and cordectomy) involves resection of the laryngeal saccule, vocal fold, and arytenoid cartilage, excluding the muscular process and the rostral strip of the corniculate.[119] Subtotal arytenoidectomy involves removal of the arytenoid cartilage except for the muscular process.[120,121]

7.2.3.8 Laryngeal Hemiplegia

7.2.3.8.1 Definition

Laryngeal hemiplegia is a failure of abduction of a structurally normal arytenoid cartilage because of decreased or absent motor activity in the cricoarytenoideus dorsalis muscle, the primary arytenoid cartilage abductor. The fundamental defect is neuropathy of recurrent laryngeal nerve that innervates all of the intrinsic muscles of the larynx with the exception of the cricothyroideus. Paralysis of the cricoarytenoideus dorsalis prevents phasic abduction of the arytenoid cartilages during inspiration or maintained abduction of the cartilages during exercise. Denervation of the arytenoideus transversus, cricoarytenoideus lateralis, ventricularis, and vocalis also prevents adduction of the arytenoids and slackening of the vocal folds.[94]

7.2.3.8.2

Causes

In the majority of cases no cause for the laryngeal paralysis is found; thus it has been termed *idiopathic laryngeal hemiplegia* (ILH). Most of the clinically detectable cases of ILH involve the left recurrent laryngeal nerve. ILH is a manifestation of a generalized distal axonopathy affecting all long nerves in large-statured horses. The left recurrent laryngeal nerve is the longest nerve in the horse and typically the only one in which axonopathy leads to a clinically evident deficit. Other theories advanced to explain the recurrent laryngeal neuropathy include (1) mechanical compression or stretch of the left recurrent laryngeal nerve as it courses over the aortic arch, (2) bacterial- or viral-induced neuropathies, and (3) vitamin deficiencies.[122] In occasional cases, laryngeal hemiplegia has been known to occur following perivascular or perineural injections, organophosphate intoxication,[123,124] lead poisoning, plant poisoning, guttural pouch mycosis, neoplasia, traumatic accidents to the neck, and paralaryngeal abscessation.[123,125]

7.2.3.8.3

Epidemiology

ILH generally is considered to be a disorder of larger-breed horses and rarely is reported in Arabians and ponies. Clinical signs usually occur after 3 years of age at a time when work begins. However, left laryngeal asymmetry has been observed endoscopically in foals.[125] Males are reported to be affected more commonly than females, although the physical size difference may be an important consideration in this regard because ILH occurs more frequently in larger horses (>160 cm in height) with long necks and narrow chests.[122] ILH has been reported more frequently in certain family lines of horses, thus causing some to propose it to be a heritable disorder.[126,127] However, the exact mode of transmission remains uncertain.

7.2.3.8.4

Pathogenesis

In ILH, distal degeneration of the nerve fibers in the left recurrent laryngeal nerve and subsequent atrophy of the intrinsic laryngeal musculature occur.[128,129] Similar, although less severe changes also occur in the right recurrent laryngeal nerve of hemiplegic horses. Mild involvement of other peripheral long nerve fibers—for example, of the distal hindlimb—also occurs. The finding of bilateral recurrent neuropathy, along with changes in other peripheral nerves, is inconsistent with the hypothesis that neuropathy is a sequela of compression or stretching of the nerve as it courses along the aortic arch. The findings, however, are not inconsistent with the development of a distal axonopathy following an energy-dependent disorder, an antioxidant disorder, or a filamentous neuropathy.[130]

7.2.3.8.5

Pathophysiology

Inadequate abduction of the arytenoids provides an inspiratory resistance to air flow. In experimentally induced hemiplegia, a significant increase in inspiratory or expiratory resistance at rest is not evident. However, during moderate exercise intensities, a significant increase in inspiratory resistance and a subsequent inspiratory airflow limitation develops.[131] The effect of this limitation on gas exchange has been evaluated. During eupneic breathing, no detectable alterations in gas exchange occur. However, during exercise, the physiologic hypercapnia and hypoxemia normally found worsens.[132,133] The ensuing hypoxemia may contribute to the exercise intolerance. The inspiratory resistance increases the work of breathing and *may* predispose to the development of respiratory muscle fatigue.

7.2.3.8.6

Clinical Signs

Most horses with unilateral laryngeal hemiplegia have a history of exercise intolerance and the production of an inspiratory noise described as a whistle or a roar. In contrast, horses with bilateral laryngeal paralysis may show respiratory distress and require emergency tracheostomies. In cases of bilateral paralysis secondary to toxins (e.g., organophosphate overdose), clinical signs may not be apparent for several weeks following the toxic insult.[134] 307 308

7.2.3.8.7

Diagnosis

Physical examination and palpation of the larynx may reveal atrophy of the cricoarytenoideus dorsalis muscle. The slap test has been used to evaluate the adductor function of the intrinsic laryngeal muscles. In normal horses, when one slaps the saddle area of the horse, contralateral arytenoid cartilage adduction occurs. This adduction is detectable endoscopically or by palpation of the larynx during the procedure. The reflex is absent in horses with idiopathic recurrent laryngeal neuropathy.[135] However, the demonstration of a normal laryngeal reflex when the horse is at rest does not indicate that the horse is completely free of laryngeal hemiplegia.[126] Ultimately, the clinician usually makes the diagnosis by an endoscopic examination wherein one observes asymmetric positioning or range of motion of the arytenoid cartilages and relaxation of the vocal folds on the affected side. Box 7-3 provides a proposed grading scheme and may aid in the decision for surgical intervention. For example, horses with grade IV can be expected to benefit from surgery, whereas horses with grades I and II usually are not compromised during exercise and thus are not good surgical candidates. Horses with grade III are considered suspect, some of these horses demonstrating dynamic collapse of the airway and thus requiring surgical intervention. Ideally, one should perform endoscopic examination of the horse during treadmill exercise to ascertain the importance of slight asymmetry at rest in the production of exercise intolerance. A recent study documented progression of laryngeal hemiplegia, as judged by clinical signs and endoscopic examination, in 15% of horses.[136] The mean age of onset of progression was 7 years.

7.2.3.8.7.1

BOX 7-3 GRADING SCHEME FOR LARYNGEAL ANATOMY

Grade I: Synchronous full abduction and adduction of left and right arytenoid cartilages.

Grade II: Asynchronous movement such as hesitation, flutters, adductor weakness of the left arytenoid during inspiration or expiration or both, but full abduction induced by swallowing or nasal occlusion.

Grade III: Asynchronous movement of the left arytenoid during inspiration or expiration or both, but full abduction not induced and maintained by swallowing or nasal occlusion.

Grade IV: Significant asymmetry of the larynx at rest and lack of substantial movement of the left arytenoid.

From Ducharme NG, Hackett RP: The value of surgical treatment of laryngeal hemiplegia in horses, *Compend Cont Educ Pract Vet* 13:472, 1991.

7.2.3.8.8 Treatment

Surgical correction of the airflow obstruction is necessary. Laryngoplasty, a prosthesis that maintains the affected arytenoid in abduction, is implemented most commonly. Complications associated with the surgery include failure to maintain abduction of the arytenoid cartilage, dysphagia leading to coughing while eating or rarely aspiration pneumonia, chronic infection of the prosthesis leading to a suture sinus, ossification of cartilage, esophageal obstruction, intralaryngeal granulomatous polyps, right-sided laryngospasm during exercise, laryngeal edema, and chondritis.[137] Ventriculectomy, surgical ablation of the lateral ventricles in an effort to induce adhesions between the vocal cords and laryngeal walls, also has been performed, singly or with the laryngoplasty. Prosthetic laryngoplasty prevents the increase in inspiratory resistance and flow limitation during moderate exercise.[132] However, ventriculectomy alone fails to alleviate the increased inspiratory impedance during exercise.[133] Surgical procedures that attempt to restore innervation to the cricoartyenoideus dorsalis muscle minimize the risk of serious postoperative complications. Described techniques include transplantation of a nerve-muscle pedicle into the cricoartenoidus dorsalis muscle, implantation of the cut end of the second cervical nerve into the left cricoarytenoideus muscle and anastomosis of the first cervical nerve to the abductor branch of the left recurrent laryngeal nerve.[137–139] A modest improvement was notable in the experimental models but a report of nerve-muscle pedicle graft in racehorses revealed results comparable to those of prosthetic laryngoplasty.[140] Reinnervation of the cricoarytenoideus muscle following nerve-muscle pedicle grafting takes 6 to 12 months depending on the amount of muscle atrophy and thus is used primarily in young, unraced horses or in horses in which a rapid return to athletic performance is not necessary.

In horses with bilateral laryngeal paralysis, tracheostomy may be required until resolution or lessening of paralysis occurs. Affected horses should not be stressed or subjected to undue movements. The clinician should institute broad-spectrum antimicrobial and antiinflammatory therapy.

7.2.3.9 *Streptococcus equi* Infections (Strangles)

7.2.3.9.1 Causes

Streptococcus equi subspecies *equi,* a gram-positive β-hemolytic bacterium of the Lancefield Group C, is 308
the causative agent of strangles, a highly contagious disease of equidae. The disease was recognized in the 309
thirteenth century and occurs worldwide.[141] Recent multilocus enzyme electrophoresis studies have confirmed a close genetic relationship of *S. equi equi* and *S. zooepidemicus,* indicating that the former is a clone derived from the more genetically diverse *S. zooepidemicus*.[142] This finding has led to the recommendation that *S. equi equi* be reclassified as a biovar of *S. zooepidemicus*.[143] Although isolates of these two organisms show greater than 92% DNA homology, immunity is species specific: immunization with *S. zooepidimicus* does not protect against challenge by *S. equi equi*.

S. equi equi (hereafter referred to as *S. equi*) is not a normal inhabitant of the equine upper respiratory tract and does not require prior viral infections for successful colonization and infection.[144] Based on morphologic features of the bacterial colony, three strains of the organism occur that differ in virulence. The typical and highly virulent encapsulated *S. equi* strains produce golden, honey-colored mucoid colonies on blood agar. Atypical *S. equi* colonies exhibit a matte appearance within 24 hours of incubation.

Nonencapsulated colonies are glossy, dry, and small.[145] Differences in the hyaluronic acid content of the capsule are responsible for the morphologically distinctive features of *S. equi* colonies.

Laboratory diagnosis of Lancefield group C streptococci *(S. equi, S. zooepidemicus, S. equisimilis)* traditionally is based on fermentation patterns of lactose, sorbitol, and trehalose. Typical *S. equi* isolates fail to ferment any of these sugars, whereas atypical *S. equi* isolates may ferment lactose or trehalose but not sorbitol.[146] In some laboratories, polymerase chain reaction (PCR) assays aid in confirming *S. equi* isolates.[147]

7.2.3.9.2 Epidemiology

The infection occurs primarily in horses 1 to 5 years old but is not restricted to this age group. Foals up to 3 months of age born from immune mares are known to be resistant to the development of strangles.[148] In susceptible equine populations, morbidity is nearly 100%, whereas mortality is low (up to 10%) if appropriate therapy is instituted.[149] Once having been infected, approximately 75% of the horses are immune to the organism for 4 years.[150] In another study, 83% of young horses affected with clinical strangles as foals were resistant to co-mingling exposure 6 months later.[151] Immunity is not lifelong: epidemiologic studies report attack rates in horses greater than 3 years of age of 18%, 29%, and 35%.[149,152,153]

The organism is transmitted (1) via direct contact with nasal secretions or lymph node discharges from infected horses or (2) via exposure to fomites such as contaminated equipment, pails, halters, leads, brushes, clothing, horse vans, or stalls. Recent additions to a stable are most often the cause of a strangles outbreak because a recovering horse may shed the organism for several weeks. In closed herds, epidemics have been attributed to exposure of horses to asymptomatic chronic carriers of the organism. Such horses harbor the organism in the guttural pouches for as long as 39 months in the absence of clinical signs. Other sites of long-term carriage of the organism include the paranasal sinuses.[154]

The organism also can survive for long periods in the environment depending on the temperature and the substrate. Jorm[155] found that *S. equi* survived for 63 days on wood at temperatures of 2° C and for 48 days on glass or wood at temperatures of 20° C. A 1:200 dilution of phenol and disinfectants such as povidone-iodine, chlorhexidine, and glutaraldehyde kill the organism within 90 minutes.

Although the organism traditionally is thought to infect only equidae, a fatal pneumonia attributed to *S. equi* infection in a dromedary camel was reported recently.[156] In the literature on human beings, descriptions of two cases of *S. equi* bacteremia exist, but infections in human beings are considered rare.[157]

7.2.3.9.3 Pathogenesis

After infective droplets are inhaled or ingested, the organism adheres to the epithelial cells of the buccal and nasal mucosa of the horse. Within hours of adhesion, the organism has translocated below the mucosa and gained access to the local lymphatics and lymph nodes where replication occurs extracellulary.[141] Spread of the organism to sites other than the upper respiratory tract lymphoid tissue may occur by hematogenous or lymphatic pathways.

At least three virulence factors of *S. equi* contribute to its pathogenicity and include the hyaluronic acid capsule, the M-like protein, and a leukocidal toxin.[158] The hyaluronic acid capsule possesses a strongly negative charge and apparently repels phagocytic cells. Nonencapsulated strains of *S. equi* are able to colonize the surface of the upper respiratory tract and stimulate production of serum antibody but are unable to induce detectable pathologic changes in the retropharyngeal and submandibular lymph nodes.[159] The second virulence factor, the M-like protein (SeM), is a 58-kd cell wall antigen. This protein functions by limiting deposition of complement components (C3b) on the bacterial surface and preventing activation of the alternative complement pathway. SeM also binds fibrinogen and impairs neutrophil killing of the organism.[142] The M-like antigen also appears to be important for adherence of the organism to the oropharyngeal epithelium. Another recently identified M-like protein, SzPSe, exhibits antigenic cross reactivity with the M-like proteins of *S. zooepidemicus*. Its contribution to the virulence of *S. equi* is currently unknown.[142]

Additional factors that may contribute to the pathogenicity of *S. equi* include extracellular proteins that are mitogenic for peripheral blood mononuclear cells.[160] These mitogenic factors have been hypothesized to 309
induce release of interleukin-1 (IL-1) and tumor necrosis factor α from antigen-presenting cells 310
(macrophages, monocytes) and to contribute to the development of fever, malaise, neutrophilia, and hyperfibrinogenemia.[160]

7.2.3.9.4 Clinical Signs

The incubation period ranges from 2 to 6 days. In typical cases, horses are febrile, exhibit malaise, and develop a serous nasal discharge that becomes mucopurulent. Submandibular and retropharyngeal lymph nodes are initially firm but become fluctuant before rupturing 7 to 10 days after the onset of signs. Lymphadenopathy may be asymmetrical and may become so severe that dysphagia and respiratory distress ensue. Swelling of the throat-latch area or of Viborg's triangle may be apparent. The affected horse may stand with its neck stretched out and be reluctant to swallow. A soft moist cough may be heard. The average course of the syndrome is 23 days.[144]

In atypical *S. equi* infections, a mild inflammation of the upper respiratory tract occurs and is characterized by a slight nasal discharge, cough, and fever. Abscessation of the lymph nodes occurs only in a small number of the cases.[145,146,161]

7.2.3.9.5 Clinical Pathology

A marked neutrophilic leukocytosis, hyperfibrinogenemia, and an anemia of chronic infection are found in typical strangles cases.

7.2.3.9.6 Diagnosis

Diagnosis usually is based on clinical signs and the isolation (culture) or detection (PCR) of *S. equi* from a lymph node, a nasopharyngeal swab, or lavage fluid from the guttural pouches. Blood cultures may become positive for *S. equi* on days 6 to 12 following infection.[162]

Identification of chronic asymptomatic carriers can be difficult. In one recent study, endoscopic abnormalities in the guttural pouches were evident in most asymptomatic carriers.[163] However, the absence of visible pathologic signs in one asymptomatic carrier emphasizes the need to obtain samples for microbiologic studies. When PCR and culture results from asymptomatic carriers were compared, many more samples were found to be positive using PCR than with culture alone.[164]

7.2.3.9.7 Treatment

Treatment is a function of the stage of the disease. Sweeney, Benson, Whitlock, et al.[165] suggested a treatment protocol that is outlined next. Penicillin is the drug of choice, although *S. equi* is sensitive to oxytetracycline and the potentiated sulfonamides.[141,154]

The treatment plan is as follows:

1. For horses exposed to the organism, penicillin therapy is indicated to prevent seeding of the pharyngeal lymph nodes. Antimicrobial therapy should continue for as long as the horse remains exposed to the organism. Once the therapy stops, a risk exists that the horse may develop strangles.

2. For horses exhibiting signs of infection in the absence of lymph node abscessation, penicillin G therapy can arrest the progression of the disease. One should isolate the horses during their treatment protocol.

3. For horses exhibiting evidence of lymph node abscessation, administration of penicillin slows the progression of lymph node abscessation and generally is contraindicated. Hot-packing the area(s) promotes abscess formation. Once achieved, the clinician should lance the abscess and flush it with a 2% tamed iodine solution. One should treat horses in isolation.

4. For horses that are systemically ill or that develop complications such as dysphagia and respiratory distress require supportive care in addition to high levels of intravenous penicillin. This therapy may entail intravenous fluid therapy, a tracheostomy, nonsteroidal antiinflammatory drugs, and feeding via the nasogastric tube.

7.2.3.9.8 Sequelae

Complications most frequently result from metastasis of the organism to other organ systems with the formation of purulent foci.[165] These complications include the following:

1. Internal abscessation of the mesentery or of parenchymatous organs. The causes of internal abscessation are not known, although inadequate antimicrobial therapy during respiratory catarrh and lymphoid abscessation may be contributory.[166] The horse may have a history of intermittent colic, periodic pyrexia, anorexia, depression, and weight loss. The clinician should direct diagnostic techniques, including rectal palpation, thoracic radiography, thoracocentesis, abdominocentesis, ultrasonography, computed tomography, and nuclear scintigraphy,[167] at determining the location of the abscess. Cases of internal abscessation can be difficult to differentiate from neoplastic causes of weight loss and colic because both processes may induce similar abnormalities in the peritoneal fluid (leukocytosis and hyperproteinemia). Differentiation between the two processes may not be possible

unless exfoliated neoplastic cells are identified.[168] Hematologic and serum biochemical abnormalities in cases of internal abscessation include (1) a neutrophilic and monocytic leukocytosis, (2) hyperfibrinogenemia, (3) hyperglobulinemia and hypoalbuminemia, and (4) hypocalcemia.[166,168] However, these changes are not unique to abscesses and may not be found in horses with intraabdominal neoplasms.[168] Thus the diagnosis of internal abscessation represents a medical challenge. Once one confirms the diagnosis, long-term penicillin therapy is indicated and may be required for several months. Clinical signs, rectal palpation, repeated abdominocentesis, and multiple complete blood counts (CBCs) are useful to monitor the progress of therapy.

2. Purpura hemorrhagica. This aseptic vasculitis occurs following reexposure to *S. equi* by natural
infection or following vaccination. In horses with purpura hemorrhagica, IgA titers to the SeM and to 310
nonspecific proteins in the *S. equi* culture supernatant (SC-P) are significantly greater than those 311
titers found in horses with uncomplicated strangles.[169] Furthermore, the isolation of immune complexes consisting of IgA and M-like proteins in the sera of horses with purpura hemorrhagica has led to the suggestion that this isotype is involved in the development of purpura.[169,170] The immunologic basis for the increase in serum IgA levels is not known: possible explanations include uncontrolled expansion of B cell populations that produce IgA against antigens of *S. equi* or failure of IgA removal mechanisms because of hepatic dysfunction. In the horse, purpura hemorrhagica has been likened to Henoch-Schönlein purpura, an immune complex–mediated disease of human beings.[170]

   The clinical signs of purpura vary and range from a mild transient reaction to a severe and fatal form. Horses with purpura develop pitting edema of the limbs, head, and trunk and petechiation and ecchymoses of the mucous membranes. Horses also may have colic following edema and hemorrhage of the bowel. The vasculitis may cause skin sloughing and infarcts of skeletal muscle. Death may ensue as a result of pneumonia, cardiac arrhythmias, renal failure, or gastrointestinal disorders.

   Confirmation of diagnosis is by skin biopsy characterized as a leukocytoclastic vasculitis, isolation of the organism, or demonstration of elevated IgA titers to *S. equi*. Treatment entails administration of intravenous penicillin (20,000 IU/kg 4 times daily), dexamethasone (0.1 mg/kg intravenously or intramuscularly), intravenous fluids, and antiinflammatory drugs. Clinical recovery occurs as the source of the antigen is removed and as the immune response is suppressed. Coincidental with recovery is the production of IgG to *S. equi* antigens.[169]

3. Guttural pouch empyema and chondroid formation (see the previous discussion).

4. Septicemia and the development of infectious arthritis, pneumonia, and encephalitis. These conditions warrant a poor prognosis.[171]

5. Retropharyngeal abscessation. Upper respiratory tract obstruction may cause the horse to develop respiratory distress and dysphagia. Endoscopy of the nasopharynx demonstrates collapse of the nasopharynx, deviation of the larynx, or drainage of purulent material into the nasopharynx when external pressure is applied to the parotid region.[172] Radiographs demonstrate a soft tissue density in the retropharyngeal area, thickening of the roof of the pharynx, reduction in the diameter of the pharyngeal airway, and distortion or compression of the guttural pouches, pharynx, and trachea.[173]

The retropharyngeal abscess may rupture into the pharynx and cause a secondary pneumonia or may rupture dorsally into the guttural pouches.[165,172,173]

6. Laryngeal hemiplegia. The condition occurs when abscessed lymph nodes encroach on the recurrent laryngeal nerve.[174]
7. Tracheal compression following abscessation of the cranial mediastinal lymph nodes. Tracheal compression has been reported. The horse may show respiratory distress or exhibit stertorous breathing. Laryngeal hemiplegia may be an additional complication if the abscess compressing the trachea involves the recurrent laryngeal nerves.[174]
8. Endocarditis or myocarditis following abscess formation.
9. Agalactia in periparturient mares.
10. Suppurative necrotic bronchopneumonia, which may result in death.
11. Abscess formation in the central nervous system.[175]
12. Myopathies. Two types of muscle disorders associated with *S. equi* infection have been described recently. One fatal form is characterized by a vasculitis and infarction of skeletal muscle and pulmonary and gastrointestinal tissues. Horses typically have signs of colic and usually are euthanized because of unrelenting pain. Postmortem examination reveals muscle infarctions that are compatible with purpura hemorrhagica. The second type of muscle disorder affects Quarter Horses that have malaise, significant muscle atrophy, and chronic active rhabdomyolysis. Immunocytochemical stains of fast-twitch fibers are positive for equine IgG. Horses responded to treatment with penicillin and dexamethasone with the muscle mass normalizing within 2 months.[176]

The clinician should follow these control measures to reduce transmission of *S. equi* during an outbreak[177]:

1. Prevent spread of infection to horses on other premises and to new arrivals immediately by stopping all movement of horses on and off the premises.
2. Identify symptomatic and asymptomatic carriers by sampling nasopharygneal or guttural pouch regions at weekly intervals and testing for *S. equi* by culture and PCR.
3. Isolate infectious horses from those screened negative for *S. equi*. Cordon off the isolation area and have infectious horses looked after by a dedicated staff wearing protective clothing and footgear. Disinfect stalls, aisles, and equipment.
4. Once clinical signs have disappeared, perform at least three consecutive swabs or lavages for *S. equi* culture, coupled with endoscopic examination of the guttural pouches to confirm that horses are noninfectious.

7.2.3.9.9 Prevention

Vaccines currently available include Strepguard with Havlogen (*S. equi* extract); Strepvax II (aluminum hydroxide adjuvanted *S. equi* extract), and Pinnacle I.N. (an attenuated live culture of *S. equi*). None of the vaccines guarantees prevention of strangles in vaccinated horses. Parenteral (killed) vaccines induce strong 311 312

serum bactericidal activity, but these antibodies are not necessarily protective because mucosal immunity plays a significant role in the resistance to infection.[178] In contrast, mucosal immunization induces a combination of systemic and local responses associated with the production of a greater variety of immunoglobulin isotypes and specificities that closely mimic those induced by natural disease. Although intranasal vaccines are expected to produce fewer adverse reactions than parenteral vaccines, lethargy, inappetence, fever, lymphadenopathy, lymph node abscessation, purpura hemorrhagica, and intramuscular abscesses have occurred after vaccination. One should not administer intranasal vaccines concurrently with other parenteral injections because of the risk of abscess formation at the site of the intramuscular injection. One should wash one's hands thoroughly following vaccination. Vaccination of infected horses during an outbreak on a farm may be associated with the development of purpura hemorrhagica. Because of the lack of scientific studies, whether the clinician should implement vaccination in the face of an outbreak is uncertain. During vaccination, effective immune response takes 7 to 10 days to develop.

7.2.4 VIRAL INFECTIONS

Viruses of known pathogenicity to the horse that produce or are associated with respiratory tract disease include equine influenza virus, EHV1, EHV2, EHV4, equine arteritis virus (EAV), and equine rhinovirus A and B.

7.2.4.1 Equine Influenza

7.2.4.1.1 Causes

The influenza viruses are enveloped myxoviruses containing single-stranded RNA. Based on the internal nucleoproteins and matrix antigens, influenza viruses have been classified as three types: A, B, and C. Types B and C infect only human beings, but type A infects many different species, including human beings, horses, swine, and avian species.[178] Natural cross-species infections have occurred between human beings and swine, and experimental infection of human beings with equine influenza virus (subtype 2) is possible, although natural infections do not occur.[179] Type A is classified further into subtypes based on the surface antigens, the hemagglutinin (H) and neuraminidase (N). Two subtypes are recognized as infectious for the horse: subtypes H7N7 and H3N8. Subtype H7N7 was first isolated in Prague in 1956 and has been called equine-1 influenza (A/equine/Prague/56). Subtype 1 is thought to have disappeared from horses worldwide because an isolate has not been confirmed since 1980. Subtype H3N8 was first isolated in Miami in 1963 (prototype) and was designated as equine-2 influenza (A/equine/Miami/63). Several variants of subtype 2 (antigenic drift) have been identified and include A/equine/Fontainebleau/79, A/equine/Kentucky/81, A/equine/Saskatoon/90, and A/equine/Newmarket 2(N2/93).[178,180,181] Compared with the human influenza virus, the equine influenza virus is stable antigenically, not experiencing major antigenic shifts. This stability has been postulated to result from the shorter life span of horses relative to human beings and the lower mutation pressure placed on the equine influenza viruses because of low specific antibody titers.[179]

7.2.4.1.2 Epidemiology

Influenza most commonly affects 2- and 3-year-old horses and may be the most common cause of respiratory illness in racehorses, with some tracks experiencing influenza outbreaks 2 to 3 times within a racing season.[180–182] This phenomenon may reflect poor ventilation systems (closed shedrows), lack of

adequate immunization protocols, and rapid transmission of the virus from exercise ponies to racehorses.[180] The reservoir of equine influenza virus between epizootics remains unknown. Some speculate that the virus is maintained in the horse population itself and that asymptomatic carriers shed virus when stressed. Alternatively, the virus may be harbored in other species such as birds, which are asymptomatic but shed the virus in their feces.[179]

7.2.4.1.3

Pathogenesis

The incubation period is 1 to 3 days, with the virus infecting the upper respiratory tract and the lungs to a lesser extent. Healthy respiratory tract epithelium is ciliated and contains mucus that forms a protective layer over the cell surface. The mucus normally acts as a mechanical barrier between air and tissue and contains antibody and protein substances that deter the attachment of viral particles to the epithelium.[183] Neuraminidase activity of the viral particles alters the efficiency of the mucociliary apparatus, allowing the virions to attach via hemagglutinin antigens to sugar groups (sialic acid) on the surface of the epithelial cells. The epithelial cell internalizes the bound virus and surrounds it with an endosome. However, in the mildly acidic conditions of the mature endosome, the hemagglutinin antigen protein becomes activated and promotes fusion of the viral and cellular membranes, leading to release of the nucleocapsid into the cytoplasm.[184] Cell necrosis and desquamation follow viral replication within the respiratory tract epithelium. Exposure of irritant receptors causes hypersecretion of submucosal serous glands and further damage to the mucociliary apparatus. Inflammation leads to massive lymphocyte infiltration and edema. Recovery of the normal epithelial architecture can require more than 6 weeks.[185] Humoral and cellular immunity are important in providing protection against viral disease: IgA blocks viral penetration but is not bactericidal; certain IgG isotypes, IgGa and IgGb, opsonize the virus particles and enhance phagocytosis.[186]

7.2.4.1.4

Clinical Signs

312

Signs of influenza appear 3 to 5 days following exposure to the virus. Horses exhibit a sudden onset of fever 313
(103° to 105° F), which may be biphasic; a serous nasal discharge; anorexia; depression; and a dry, deep cough. Some horses exhibit myalgia, myositis, and limb edema and are thus reluctant to move.[179] A mild form of azoturia (myoglobinuria) occurs in some cases. One may find submandibular lymphadenopathy, as well as endoscopic evidence of pharyngitis and tracheitis. A mild bronchitis with minimal changes in lung sounds may occur. From experimental studies, inoculation with A/equine-1 produces a milder (subclinical) syndrome unless the animal is stressed before infection, whereas A/equine-2 usually generates the typical clinical signs. The course of the infection usually lasts 2 to 10 days in uncomplicated cases. Exercise exacerbates the clinical signs.[187] Secondary bacterial infections may occur, and donkeys and mules appear to have greater susceptibility to secondary infections than horses.[188] Horses remain infectious for 3 to 6 days after the last signs of illness.

In young foals, influenza is severe, producing signs of viral pneumonia, which may lead to death within 48 hours.

7.2.4.1.5

Clinical Pathology

Horses initially may exhibit a lymphopenia followed by a monocytosis.

7.2.4.1.6

Diagnosis

The clinician may diagnosis equine influenza by two methods:

1. Detection of virus. Based on studies of influenza outbreaks, viral culture and isolation alone from nasopharyngeal swabs appears to be the least sensitive method for diagnosing influenza,[180] probably because the chances of viral isolation are greater when samples are collected within the first 24 hours.[182] However, a stallside assay (Directigen Flu-A test, Becton Dickinson, Franklin Lakes, New Jersey), allows rapid detection of influenza antigen and an immediate diagnosis.[185] Detection of viral particles in materials obtained from nasopharyngeal swabs via PCR permits diagnosis of influenza infections within 48 hours of sample submission.
2. Serologic testing. Several diagnostic methods for detecting influenza virus antibodies in the horse are available and include complement fixation, hemagglutination inhibition, single radial hemolysis, viral neutralization, and enzyme immunoassay.[189] Acute and convalescent serum samples are needed to establish a definitive diagnosis, and although viral neutralizing antibodies may be detectable within a week of infection, the horse may take up to 28 days to exhibit a rise in hemagglutination titers.[179] Serologic testing has been considered to be a sensitive method for diagnosing influenza outbreaks, although in one epidemic, approximately 24% of horses with clinical signs of influenza failed to seroconvert.[180]

7.2.4.1.7

Treatment

Treatment is primarily symptomatic, ensuring that the horse continues to maintain adequate hydration and is not subjected to undue stresses. Nonsteroidal antiinflammatory drugs may be indicated to reduce the fever, eliminate the myalgia, and improve the appetite. The risk is that the owner will return the horse to strenuous exercise before the horse has rested a sufficient time. Horses that suffer severe infections may be unfit for competition for 50 to 100 days after infection. During the infection, frequent examinations of the respiratory tract are indicated to detect the development of secondary complications such as pneumonia, pleuropneumonia, and myocarditis.

7.2.4.1.8

Prevention

Regular vaccination significantly reduces the population at risk. In fact, the suggestion has been made that at least 70% of the equine population (horses, ponies, donkeys) should be vaccinated to prevent epidemics of influenza.[190] Killed and modified live vaccines are commercially available. The inactivated vaccines contain both subtypes of influenza virus and some of their strain variants (e.g., A/equine-2/KY 81). Equine subtypes 1 and 2 do not immunologically cross-react: exposure to one subtype does not protect against exposure to the other. The modified live vaccine (Flu Avert, Heska, Fort Collins, Colorado) contains only A2 strains and is administered intranasally.

In one study the use of a killed vaccine reduced neither the rate of respiratory tract disease nor the severity of clinical scores compared with nonvaccinates.[191] This vaccine failure may be a function of the number of boosters horses received before infection and of the strain of A2 contained within the vaccine.

Little data is currently available concerning the performance of the modified live vaccine during influenza outbreaks. From experimental trials, the vaccine appears to have phenotypic stability, is efficacious against heterologous virus challenge, and can be administered safely to strenuously exercised horses.[192,193] The modified live vaccine is not recommended for pregnant mares.

Vaccination of young athletic horses is recommended more frequently (at 4- to 6-month intervals) than for horses that have received regular boosters for years. Vaccinating foals before 6 months of age may be ineffective in inducing an antibody response to influenza (killed vaccine) because of interference by maternally derived antibodies.[194,195] Some undesirable side effects of vaccination occur, including fever, depression, pain, swelling at the vaccine site, and muscular stiffness, but these usually resolve within 1 or 2 days.[182] Administering two intranasal vaccines simultaneously is not recommended.

7.2.4.1.9 Sequelae

Secondary bacterial pneumonia and pleuropneumonia are potential complications that may follow viral respiratory diseases in horses that have not been rested adequately before being returned to training or that have undergone other potentially stressful events such as long trailer rides. Myocarditis, pericarditis, and 313
cardiac arrhythmias are other possible sequelae to influenza infections. 314

7.2.4.2 Equine Herpesvirus Types 1 and 4

7.2.4.2.1 Causes

Currently, five equine herpesviruses are recognized as causing disease in horses. Three are classified as α-herpesviruses (EHV1, EHV3, and EHV4), and two are grouped with the γ-herpesviruses (EHV2 and EHV5). EHV4, formerly called EHV1 subtype 2, serologically cross-reacts with EHV1 but is genetically distinct from that virus.[196] EHV1 and EHV4 share many common clinical features. EHV1, in addition to causing respiratory disease, also causes abortions, myeloencephalitis, and neonatal deaths. EHV4 is associated predominantly with respiratory disease in young horses but *sporadically* causes abortion, neonatal deaths, and neurologic disease.[197–200]

7.2.4.2.2 Epidemiology

EHV1 and EHV4 may persist within a herd because of recrudescence of latent infections during periods of stress or immunosuppression. Dexamethasone or cyclophosphamide administration is a reliable reactivation stimulus for viral shedding in experimental studies.[201] For some years the site of viral persistent was unknown. However, in a study of 40 abattoir horses, EHV1 and EHV4 were detectable by PCR methods in the bronchial lymph nodes of 88% of the horses examined. Of the trigeminal ganglia examined in nine of the horses, one was found to contain only EHV1, four had detectable EHV4 in the ganglia, and three had evidence of EHV1 and EHV4.[202] EHV2 also was isolated from all of the horses examined, leading some researchers to speculate that EHV2 activates the promoter gene of EHV1.[203] In addition to the clinical trials, experimental studies of EHV1 and EHV4 also have provided data supporting the fact that lymphoid and neural tissues are sites of viral latency.[201,203]

Realizing that virus can establish latency, one easily can understand why respiratory infections by EHV1 or EHV4 can develop in foals, weanings, and yearlings in closed herds. Immunity to EHV1 or EHV4 is short-lived (3 to 5 months) so that most horses are reinfected during their breeding or racing careers. Reexposure usually results in mild or inapparent infections, except in the case of broodmares in which reinfection may lead to abortion in the last trimester. Immunity following abortion is generally of longer duration, and in the field, repeat abortions rarely occur in the same mares. No clear relationship exists between gestational age or the level of virus-neutralizing antibody and the incidence of virus-induced abortion.[204] Perinatal disease characterized by weakness and respiratory distress is usually evident within 18 to 24 hours of birth, with foals dying within 24 to 72 hours.[205]

7.2.4.2.3 Pathogenesis

Infection occurs via inhalation of the virus or contact with infected tissues. The virus is delicate and does not survive in the environment; thus close contact appears to be important for transmission.[205] Kydd, Smith, Hannant, et al.[206] have suggested that EHV1 enters the upper respiratory tract and, in the absence of mucosal antibody, immediately infects the epithelium lining of the nasopharynx and tonsils. Subsequent events depend on whether EHV1 becomes a productive or limited infection. Productive infection results in the intercellular spread of EHV1 through susceptible cells (including leukocytes) in the stroma until the vascular or lymphatic endothelium becomes infected. Thereafter infection spreads via leukocyte adhesion to infected endothelium, leading to the development of cell-associated viremia. As a result of viremia and of inhalation of viral particles, the virus disseminates to the lower respiratory tract. In a limited infection, infected cells are phagocytized and viral antigens are processed and presented to lymphocytes in mucosal lymphoid nodules or lymph nodes. The studies of Burrell[89] and Sutton, Viel, Carman, et al.[207] have demonstrated lower respiratory tract involvement in which hyperemia and mucous accumulations develop 2 to 12 weeks after the initial infection. EHV1 also has a tropism for lymphocytes and is reported to cause immunosuppression.

The pathogenesis of EHV4 has not been investigated completely and may be similar to that of EHV1.

7.2.4.2.4 Clinical Signs

Clinical signs of rhinopneumonitis appear 1 to 3 days following infection and are indistinguishable from influenza. Horses are febrile and exhibit a cough and a serous nasal discharge, which may become mucopurulent with secondary bacterial infections. Horses develop rhinitis, pharyngitis, and tracheitis detectable endoscopically. A severe disseminated EHV1 infection that caused fever, depression, respiratory distress, and eventual death has been described in yearlings and 2-year-old horses.[208,209]

7.2.4.2.5 Clinical Pathology

An epidemiologic survey by Mason, Watkins, McNie, et al.[210] during an outbreak of EHV1 infection on a racetrack in Hong Kong documents a monocytosis in infected horses (>500 cells/μl) during the first 5 days of clinically apparent infections. In experimental infections of EHV1, a decrease in neutrophils and monocytes occurs on day 3 after infection, but the absolute values of both cell types remain within normal limits.[207]

7.2.4.2.6 Diagnosis

One may attempt viral isolation from citrated blood samples. Virus has been recovered from mononuclear cells for up to 2 weeks after infection or from nasopharyngeal swabs. PCR on clinical materials is rapid and enables distinction between EHV1 and EHV4.[211] Serologic diagnosis is made by demonstrating a fourfold increase in titers. Virus neutralization, immunoassay, complement fixation, and a radial immunodiffusion enzyme assay can detect antibodies against EHV1.[212] Postmortem examination of foals who died from 314
EHV1 or EHV4 infection revealed interstitial pneumonia, pleural and peritoneal effusions, hypoplasia of 315
the thymus and spleen, focal necrosis of the liver, and viral inclusion bodies within the hepatic parenchyma. Similar pathologic findings are observed in aborted fetuses.

7.2.4.2.7 Treatment

Treatment is supportive, minimizing stresses and ensuring adequate rest. Limited trials using antiviral drugs experimentally or clinically have been described. Acyclovir, is an acyclic nucleoside analog that inhibits viral DNA polymerases. Acyclovir is activated by virus-induced thymidine kinase before being converted to acyclovir triphosphate by cellular kinases. During outbreaks of EHV1 involving neurologic disease or neonatal deaths, acyclovir has been administered at doses ranging from 8 to 16 mg/kg orally 3 times daily to 20 mg/kg orally 3 times daily.[213,214] The efficacy of acyclovir in treating respiratory disease has not been demonstrated. One potential drawback of acyclovir use is the development of viral resistance in strains lacking thymidine kinase. Another antiviral drug, (s)-1-[(3-hydroxy-2-phosphonyl methoxy)-propyl]cytosine, or HPMPC, has been shown to be efficacious when given before EHV1 challenge in naïve foals but has not been used clinically in North America.[215]

Because evidence of immunosuppression during herpetic infections exists, the clinician should give horses broad-spectrum antimicrobials for 7 to 10 days and order rest for 4 to 6 weeks before the horse commences light exercise.

7.2.4.2.8 Prevention

Currently available vaccines are produced from EHV1 and EHV4, and although the vaccine does not prevent infection, it reduces the severity of clinical signs.

7.2.4.3 Equine Herpesvirus 2

EHV2 is a slowly replicating virus, often referred to as equine cytomegalovirus. Opinions as to the role of EHV2 in producing equine respiratory diseases have been equivocal because the virus can be recovered from various sites from ill and apparently healthy horses.[87,216] Foals that are infected experimentally with EHV2 develop pharyngitis and lymphoid hyperplasia, thus implicating this as a causative agent of chronic lymphoid hyperplasia in young horses.[87] The virus also has been isolated from young horses in race training with pharyngeal lymphoid hyperplasia.[89] EHV2 has been isolated from 2- to 3-month-old foals during outbreaks of pneumonia in Hungary, Japan, Australia, New Zealand, and in the United States.[216–220] In some of these outbreaks, EHV2 was the sole infectious agent isolated from the respiratory tract, whereas in other outbreaks, bacterial agents—*Streptococcus zooepidemicus* and *Rhodococcus equi*—complicated the pneumonitis.[219] This

has led some to speculate that if the foals are stressed or infected with a large dose of virus during a period in which maternal antibodies are waning, then the virus may invade the cells of the immune system and cause further immunosuppression. Blakeslee, Olsen, McAllister, et al.[87] reported a dose-related immunosuppression following in vitro infection of lymphocytes with EHV2, and this effect has been documented in vivo using a rabbit model.

EHV2 also has been isolated from ocular, nasal, and tracheobronchial swabs of horses with keratoconjunctivitis, implicating it in the production of this clinical sydrome.[221]

The suggestion has been made that most foals are exposed to EHV2 at 2 to 3 months of age and shed the virus for 2 to 6 months until a humoral antibody response develops and eventually is associated with low viral recovery.[216] Nearly 100% of older horses are seropositive for EHV2.[222]

After natural exposure, EHV2 is recoverable from nasal and nasopharyngeal swabs, from the kidney, bone marrow, spleen, mammary gland, salivary gland, vagina, tracheal mucus, neural tissue, and from the cornea and conjunctiva.[222,223] Leukocytes and lymph nodes draining the respiratory tract are major reservoirs of EHV2 DNA.[222]

Diagnosis of EHV2 depends on isolation of the virus, serologic evidence of an active viral infection, and the presence of clinical signs. Treatment is symptomatic. Efficacy of antiviral agents has not been examined in EHV2 infections.

7.2.4.4 Equine Viral Arteritis

7.2.4.4.1 Causes

Equine arteritis virus, an enveloped single-stranded RNA virus, is a member of the order Nidovirales and family Arteriviridae. EAV is genetically similar to coronaviruses (also a member of Arteriviridae) but has a dissimilar viral structure and complement-fixing antigen.[224] Only one strain has been identified, the Bucyrus strain, but isolates vary in virulence.[225]

7.2.4.4.2 Epidemiology

Before the 1984 epizootic of equine viral arteritis (EVA) in Kentucky, little attention was paid to this virus.[226] Most infections were assumed to be transmitted by inhalation until the important role of venereal transmission was demonstrated in those outbreaks. The virus is maintained in the equine population by long-term and short-term carriers in stallions. The duration of the carrier status ranges from several weeks to years. Testosterone is essential for maintenance of persistence. Long-term infections do not occur in colts exposed to the virus before the onset of peripubertal development or in mares.[226–228] During the carrier state, the virus is present solely in the reproductive tract, principally in the ampulla of the vas deferens. Primary exposure to the virus is presumed to be via the venereal route. Susceptible mares bred to carrier stallions almost always become infected with EAV. Viral shedding into the respiratory tract allows secondary horizontal transmission of the virus to occur.

A significant difference in seropositivity to EAV exists among the horse breeds. Approximately 84% of Standardardbreds and 93% of Austrian Warmblood stallions have circulating antibodies to EAV, whereas less than 5% of Thoroughbred and less than 1% of Quarter Horses are seropositive.[229] 315 316

7.2.4.4.3

Pathogenesis

Following intranasal challenge (aerosolization), the virus invades the respiratory tract epithelium and the alveolar macrophages. By 72 hours after infection, replicating virus are detectable in the bronchopulmonary lymph nodes, endothelium, and circulating macrophages. Dissemination of the virus by hematogenous routes allows infection of mesenteric lymph nodes; spleen; liver; kidneys; nasopharyngeal, pleural, and peritoneal fluid; and urine.[226] By 6 to 8 days after infection, the virus has localized within the endothelium and medial myocytes of blood vessels, where it causes a necrotizing arteritis, a panvasculitis.[224] The vascular lesion may be caused by a direct cytopathic effect of the virus on the endothelium and medial myocytes or from the effects of anoxia or thrombosis induced by cell damage.

With venereal transmission (by natural cover or by artificial insemination), the virus can be isolated from swabs of the rectal and vaginal mucosa during the febrile periods.

7.2.4.4.4

Clinical Signs

Clinical signs vary, ranging from severe disease to subclinical infections. The variation may be a function of host factors, such as age and immune status, and virus factors, including the virulence, the amount of infective virus, and the route of infection.[230] The incubation period ranges from 3 to 14 days (6 to 8 days if transmitted venereally). In the acute disease, horses are febrile (105° F) for 1 to 5 days, anorectic, and depressed and may cough. Other clinical signs include a serous nasal discharge, congestion of the nasal mucosa, intermandibular lymphadenopathy, conjunctivitis, lacrimation, and less frequently, corneal opacification. Edema of the sheath, scrotum, ventral midline, limbs, and eyelids occurs because of vasculitis. Other signs may include respiratory distress, stiffness, soreness, diarrhea, icterus, skin rash on the neck, and papular eruptions on the inside of the upper lip. Most adult horses recover uneventfully.

Abortions occur from the tenth to the thirty-fourth day following exposure (during the third to tenth months of gestation), but the mechanism is not known. Abortion can occur with or without preceding clinical evidence of infection.[231] EVA has not been associated with teratologic abnormalities in fetuses or foals.

Neonates may die suddenly or develop severe respiratory distress followed by death.[226,232]

7.2.4.4.5

Clinical Pathology

Infection causes leukopenia, lymphopenia, and thrombocytopenia.

7.2.4.4.6

Diagnosis

EVA is a reportable disease. Although virus may persist in the buffy coat for up to 36 days after infection, viral isolation can be difficult.[230] The clinician should submit citrated blood samples and should attempt isolation of virions from nasopharyngeal and conjunctival swabs, vaginal swabs, and semen from an

infected stallion.[233] PCR enhances viral detection and specificity. One also should attempt serologic diagnosis. Virus neutralization, complement fixation, immunodiffusion, and immunofluorescence are techniques used to demonstrate changes in antibody titers. A fourfold or greater rise in titer or a change in status from seronegative to seropositive may indicate a recent infection. Postmortem examinations of aborted fetuses do not show signs of arteritis as seen in adults. Fetuses do have evidence of edema, excessive pleural fluid, and petechiation on the mucosal surfaces of the respiratory and gastrointestinal tracts, but focal necrosis of the liver or intranuclear inclusions are not features of the disease.[225]

7.2.4.4.7 Treatment

Treatment is primarily symptomatic, keeping the horse hydrated and providing analgesics (nonsteroidal antiinflammatory drugs) as needed. Fever in stallions can lead to sperm damage and temporary infertility, so one should administer nonsteroidal antiinflammatory drugs. The clinician should isolate horses for 3 to 4 weeks to minimize the chances of transmission.

7.2.4.4.8 Prevention

Vaccination of seronegative stallions with a commercially available modified live vaccine is credited with preventing the establishment of carrier states in the stallion or with further increases in the carrier state during the 1984 epizootic in Kentucky. Stallions were bred only to mares that were vaccinated or seropositive from previous natural exposure to EVA. Following vaccination, clinical immunity was found to develop rapidly and to last for 1 to 3 years.[226] Primary vaccination does not prevent reinfection and limited shedding of virus. Clinicians should vaccinate mares 3 to 4 weeks before breeding to an EAV carrier stallion and should isolate such mares for another 3 weeks after being bred to a carrier stallion for the first time.[231] Vaccination is not recommended for pregnant mares or in foals less than 6 weeks of age. Passively derived antibodies to EAV decrease to undetectable amounts by 8 months postpartum for foals born to seropositive mares. Vaccination should be effective at this time if necessary.[234]

7.2.4.5 Equine Rhinoviruses

Among those viruses that formerly were called equine rhinoviruses—classified as members of the family Picornaviridae and genus *Rhinovirus*—two serotypes were identified. Serotype 1 recently has been renamed equine rhinitis A virus (ERAV) and has been reclassified as a member of the genus *Aphthovirus*. The reclassification is based on (1) homology of the nucleotide sequence of the ERAV genome with that of foot-and-mouth disease virus, (2) the physicochemical properties of ERAV, and (3) the production of viremia and 316
persistent shedding following ERAV infection.[235] Serotype 2 has been renamed equine rhinitis B virus 317
(ERBV) and has been reclassified as the sole member of the genus *Erbovirus*. A third serotype designated P313/75 also has been identified and currently is assigned to the family Picornaviridae. However, based on sequence similarity and serologic data, investigators have proposed that P313/75 be classified as a distinct serotype of *Erbovirus* and tentatively have named it ERBV2.[236]

Infection of horses with ERAV causes acute fever, nasal discharge, coughing, anorexia, pharyngitis, laryngitis, and submandibular lymphadenitis.[237,238] Infection produces moderate increases in the neutrophil-to-lymphocyte ratios (from 50:49 in healthy horses to 57:43 in infected horses) and in plasma fibrinogen.[238] The importance of ERAV as a cause of respiratory disease has not been recognized previously because clinical

signs may be mild and because viral isolation is difficult.[239] The incubation period is 3 to 8 days, with shedding of viral particles from pharyngeal secretions, urine, and feces a feature of the infection. Young horses are infected more commonly and in one study, 73% of 2-year olds showed serologic evidence of ERAV infection.[238]

Equine rhinovirus A has a broad host range that includes rabbits, guinea pigs, monkeys, and human beings. Experimental and epidemiologic evidence of ERAV infection of human beings exists. High antibody titers were found in the sera of 3 of 12 stable workers, whereas no ERAV antibody was found in the sera of 159 non–stable workers.[240] One can attempt diagnosis of ERAV infection by serologic testing (fourfold changes between acute and convalescent titers) or PCR identification of the virus in nasopharyngeal swabs.[239]

Equine rhinovirus B is also an equine respiratory tract pathogen. In a survey of horses with acute respiratory disease, researchers isolated ERBV from 30% of the horses sampled. Of the 28 horses from which the virus was recovered, a serologic diagnosis was made in only 6 horses. Researchers attributed the low diagnosis rate to the difficulty of initially collecting samples during the acute phase: antibody levels rise rapidly from day 6 after infection to peak between days 14 and 18.[241] Thus in contrast to ERAV, viral isolation may be the more successful diagnostic method.

The clinical significance of ERBV2 (P313/75) is unknown. ERBV2 was isolated from a horse with a history of 6 days of intermittent fever that began 4 days after an umbilical hernia operation and castration.[242] The clinical importance requires further investigation.

No vaccine is currently available for ERAV or ERBV.

7.2.4.6 Tracheal Disorders

7.2.4.6.1 Definition

Inflammations, obstructions, compressions, lacerations, and containment of foreign bodies are the predominant disorders of the trachea in the horse.[243–246] Tracheitis often accompanies viral upper respiratory tract diseases (see previous discussion) and manifests as areas of hyperemia and epithelial desquamation. Lacerations usually result from trauma, whereas compressions may result from extraluminal masses such as streptococcal abscesses or neoplasms such as lymphosarcomata or lipomata. Intraluminal obstructions may follow fibrotic stricture formation following trauma, tracheostomy, or pressure necrosis from inflated cuffs of endotracheal tubes or may be caused by granulomatous reactions within the trachea.[243] Foreign bodies, such as twigs, probably are inhaled during deglutition. Tracheal collapse may represent a congenital defect in miniature horses and ponies.[247,248]

7.2.4.6.2 Clinical Signs

Clinical signs vary and range from stertorous breathing and dyspnea to chronic and persistent coughing and bilateral nasal discharge with a foul odor. Mild manipulation of the trachea also may induce paroxysmal bouts of coughing.

7.2.4.6.3 Diagnosis

The diagnosis is made on physical examination or endoscopic evaluation of the trachea. A history of a tracheal surgery or traumatic episode should alert the diagnostician to the possibility of an intraluminal obstruction or stricture. The clinician may visualize foreign bodies on examination but may need radiographs to delineate the extent of their involvement. One also should perform radiographic examination of the thorax to determine if a concomitant pneumonia, pneumomediastinum, or pneumothorax exists.

7.2.4.6.4 Treatment

One directs treatment at the primary cause. One does not treat primary inflammations following viral infections unless a persistent fever and a secondary bacterial tracheitis and pneumonia develop. The clinician may extract foreign bodies but may require tracheotomy to retrieve them if the endoscope is not long enough. In the adult horse a 2-m endoscope is necessary to reach the level of the carina located at the fifth to sixth intercostal space. Extraluminal masses require careful drainage or excision, with the potential for spread of infection into the mediastinum. The clinician should isolate horses with *Streptococcus equi* infections from other equids. Rupture of the trachea may require temporary tracheotomy distal to the rupture to ensure patency of airflow. A 2-week course of broad-spectrum antimicrobial therapy may be indicated, especially if the mucociliary clearance mechanism is compromised. Complications such as subcutaneous emphysema, cellulitis, and pneumomediastinum usually resolve over 2 weeks. Horses with tracheal defects have a poor to guarded prognosis for return to athletic potential.

7.3 The Normal Lung

7.3.1 ANATOMY

The lungs of the horse differ from those of other domestic species in that they lack deep interlobar fissures and 317

distinct lung lobes. Superficially, however, the left lung consists of a cranial and caudal lobe, whereas the right 318 lung contains a cranial, an intermediate, and a caudal lobe.[249] The intrathoracic trachea bifurcates into the right and left main stem bronchi at the level of the fifth or sixth intercostal space and enters the hilum of each lung. At its division from the trachea, the right bronchus assumes a straighter, more horizontal position relative to the left bronchus, a configuration that may predispose the horse to develop right-sided pulmonary disorders. Each bronchus divides into lobar, segmental, and subsegmental bronchi with the eventual formation of bronchioles. In the distal part of the bronchial tree the terminal bronchioles lead into poorly developed respiratory bronchioles or open directly into alveolar ducts.[249,250] The tracheobronchial lining consists of tall columnar, pseudostratified epithelium interspersed with serous and goblet cells. The goblet cells and the underlying submucosal mucous glands function to produce mucus consisting of an outer gel and an inner sol layer.[251] Mucus serves to prevent epithelial dehydration, contains protective factors that guard against infectious agents, and is an integral part of the mucociliary apparatus. The rapid beating of the cilia moves mucus and any particulate matter to the pharynx to be swallowed. Approximately 90% of material deposited on the mucinous layer is cleared within 1 hour.

Ciliated cells decrease in frequency with successive divisions of the airways so that at the level of the bronchioles the epithelium is composed predominantly of low ciliated and taller nonciliated Clara cells.[252] Glands are also absent at this level. The bronchiolar epithelium becomes contiguous with that of the alveoli, which are characterized by two distinct cell types. Type I pneumocytes cover most of the alveolar surface with

thin cytoplasmic extensions 0.2 to 0.5 μm thick.[251] Type II cells are cuboidal and contain the characteristic lamellar cytoplasmic inclusions thought to constitute surfactant components. Type II cells also are considered to be stem cells, replacing the type I cells when damaged.

Lymphocytes are scattered throughout the pulmonary epithelium, are associated with the bronchioles and bronchi, and occur in discrete nodules or patches.[253] These cells, along with alveolar macrophages, provide an integral component of the pulmonary immune surveillance system. Macrophages are derived from blood monocytes via the interstitium and are cleared continuously from the alveoli. They are the predominant cell type recovered from the bronchoalveolar lavage in normal horses (see Table 7-1). Pulmonary interstitial macrophages are able rapidly to ingest particles introduced within the pulmonary circulation.[254] The ability of these macrophages to localize antigenic particles within the pulmonary vasculature may predispose the equine lung to development of acute pulmonary inflammation (e.g., during endotoxemia).

Additional cells within the lung parenchyma include the subepithelial and free mast cell. These cells bear IgE on their cell surface and release biogenic amines in response to specific antigen stimulation. They appear to be important in the pathogenesis of several equine pulmonary disorders, including anaphlaxis and lungworm infections.

Tracheobronchial secretions consist of substances secreted from mucous and serous glands, as well as serum transudates. The principal component of the secretions is water, with approximately equal amounts of protein, carbohydrate, lipid, and inorganic material. Contained within the protein fraction of the tracheobronchial secretions are albumin, IgA, IgG (the predominant immunoglobulin in the lower lung), lysozyme, lactoferrin, haptoglobulin, transferrin, and complement components.[251]

7.3.2 VASCULAR SUPPLY

The lung has two sources of blood flow. The major source of blood is the pulmonary circulation, a low-pressure, low-resistance system that serves primarily to deliver blood to the alveoli for participation in gas exchange but also provides nutrients to the alveolar constituents. The distribution of the pulmonary arterial flow to the various lung regions depends largely on mechanical forces: gravity and pulmonary arterial, pulmonary venous, and alveolar pressures.[255] In the standing horse, a vertical perfusion gradient of the lung has been demonstrated,[256] the most dorsal part of the equine lung being less well perfused than the ventral dependent regions. The distribution of pulmonary blood flow also is influenced by vasoactive compounds such as catecholamines, histamine, and eicosanoids and by changes in alveolar oxygen and carbon dioxide. Alterations in pulmonary vascular resistance may help to match ventilation with perfusion and optimize gas exchange.

The bronchial circulation, the second source of blood flow to the lungs, provides nutrient support to the lymphatics and vascular and airway components. Bronchial circulation provides arterial blood to the pleural surface and anastomotic connections with the alveolar capillary bed derived from the pulmonary circulation.[250] The magnitude of the anastomotic flow depends on the relative pressure in the bronchial and pulmonary microvasculature and on the alveolar pressure. Thus in the dorsal part of the lung, where pulmonary arterial flow is poor, blood flow from the bronchial circulation may be favored.[257] The degree of anastomotic bronchial blood flow through the alveolar capillaries also increases with systemic arterial hypoxemia and alveolar hypoxia.[255] The bronchial circulation undergoes hypertrophy (angiogenesis) in response to inflammatory pulmonary diseases such as chronic bronchitis, bronchiolitis, and bronchiectasis. 318

7.3.3 INNERVATION

The autonomic nervous system supplies innervation to the pulmonary structures. This nervous system influences (1) airway smooth muscle tone, (2) secretion of mucus from the submucosal glands, (3) transport of fluid across airway epithelium, (4) permeability and blood flow in the bronchial circulation, and (5) release of mediators from mast cells and other inflammatory cells.[258] In the horse the autonomic nervous system can be classified functionally into three categories: (1) parasympathetic, (2) sympathetic, and (3) nonadrenergic noncholinergic (NANC) pathways.[259] The vagus nerve is an integral component of the parasympathetic and NANC systems. The vagus nerve not only contains the efferent fibers of these pathways, which help to alter airway resistance, lung volume, and compliance, but also contains the afferent fibers the central input of which regulates the pattern of breathing. Stimulation of the parasympathetic fibers within the vagus nerve (i.e., the efferent limb) releases acetylcholine from the postganglionic fibers and combines with the muscarinic receptors of the airway smooth muscle to cause bronchoconstriction. Yet because atropinization (antagonism of muscarinic receptors) does not normally change airway resistance, the parasympathetic system appears to exert little influence on resting airway tone in the *healthy* horse.[260] However, vagal efferents are important in reflex bronchoconstriction during pulmonary disease.

As described previously, the vagus nerve also contains afferent nerve fibers that transmit information detected by three types of pulmonary mechanoreceptors: (1) the slowly adapting receptors, (2) the rapidly adapting receptors, and (3) the nonmyelinated C fibers. The receptors relay information to the central respiratory neurons located within the ventral medulla and pons. Changes in breathing depth and frequency occur in response to mechanical deformations or chemical stimulation of these receptors. Thus these receptors mediate the tachypneic breathing pattern that occurs in response to inhalation of irritant substances. Stimulation of these receptors also influences airway smooth muscle tone,[261] inducing reflex bronchoconstriction in response to inhaled irritants.

In the lung, α- and β-adrenergic receptors mediate sympathomimetic effects. Postsynaptic fibers course from the sympathetic ganglion to airway smooth muscle where released norepinephrine interacts with α- and β-receptors. Postganglionic sympathetic fibers also innervate parasympathetic ganglia. The released norepinephrine inhibits cholinergic neurotransmission.[259] However, numerous β_2-adrenergic receptors are distributed throughout the pulmonary parenchyma that lack innervation by the sympathetic fibers. Circulating catecholamines are probably important in activating these receptors and in causing subsequent bronchodilation. It is of interest that β_2-adrenergic stimulation does not alter airway diameter in the healthy horse[262] but does increase airway caliber in horses with recurrent airway disease. β-agonists also promote ion transport and water secretion across human airway epithelium (in vitro) and may cause similar effects in vivo in the horse. This effect would benefit mucociliary clearance by increasing the sol component of the mucus. In addition, β-agonists stimulate surfactant secretion by type II pneumocytes, inhibit antigen-induced mast cell degranulation, and modulate cholinergic neural transmission.[258] Such effects remain to be demonstrated in the horse, however.

α-Adrenergic receptors also exist in the equine lung, but their stimulation induces bronchoconstriction only in heavy and not in normal ponies.[263] This finding suggests that, in health, these receptors are probably unimportant in the regulation of bronchomotor tone.

An additional autonomic pathway, the NANC inhibitory system, also has been demonstrated in the equine lung, and its fibers course within the vagus nerve.[259] Although the mediators involved in neural transmission have not been identified definitively, some speculate that vasoactive intestinal peptide or peptide histidine isoleucine or

both may be the neurotransmitters.[264] Stimulation of this pathway causes a 50% reduction in smooth muscle tone and thus exerts a vasodilating effect.[265] Interestingly, horses with recurrent airway disease appear to lack NANC innervation in the bronchioles, and this dysfunction may contribute to the airway hyperactivity observed.[259]

7.3.4 LYMPH DRAINAGE

Lymph drainage from the lung is accomplished by (1) the deep lymphatics, which begin at the level of the alveolar ducts and run with the conducting airway and arteries toward the hilar lymph nodes, and (2) the superficial lymphatics, which drain the visceral pleura through a plexus converging on the hilum.[251]

7.3.5 PULMONARY PHYSIOLOGY

The major function of the lung is gas exchange: diffusion of oxygen and elimination of carbon dioxide. During eupnea, an adult horse breathes at a frequency of about 12 breaths per minute and a tidal volume near 6.5 L. This represents a total minute ventilation of 77 L/min, or more than 100,000 L/day. During this same period, the resting horse consumes approximately 2.1 L/min of oxygen (3000 L/day) and produces approximately 1.7 L/min of carbon dioxide (2400 L/day).[266] Thus the lung provides an important means by which normal arterial oxygen and carbon dioxide tensions and arterial pH are maintained. In the absence of lung disease, pulmonary arterial 319
oxygenation (Pao_2) depends on the inspired fraction of oxygen (normally 0.21) and the effective level of alveolar 320
ventilation. This is approximated by a version of the alveolar gas equation:

$$PAo_2 = PIo_2\ (PAco_2)/R$$

where PAo_2 is the alveolar oxygen tension, PIo_2 is the inspired oxygen tension, $PAco_2$ is the alveolar carbon dioxide tension, and R is the respiratory exchange quotient (the ratio of CO_2 production to O_2 consumption). Because an admixture of venous blood with the pulmonary arterial circulation occurs, alveolar oxygen tension exceeds arterial oxygen tension by approximately 10 mm Hg.

In the absence of alterations in inspired oxygen tensions, arterial hypoxemia (Pao_2 <85 mm Hg) may result from basically four processes, including (1) hypoventilation, (2) diffusion impairment, (3) V/Q ($\dot{V}$ / $\dot{Q}$) inequality, and (4) shunts.[267]

Alveolar and thus arterial CO_2 levels depend on the rate of CO_2 elimination relative to its production, given by the following equation:

$$PAco_2 = \dot{V}CO_2/\dot{V}A$$

where $\dot{V}$ CO_2 is the rate of CO_2 production and $\dot{V}$ is alveolar ventilation. *Hypoventilation* is defined as inadequate CO_2 elimination relative to production, resulting in an elevated $Paco_2$ (hypercapnia, hypercarbia). Hypoventilation can result from a variety of abnormalities. A convenient diagnostic approach follows the control of breathing from (1) the respiratory center in the medulla, (2) the efferent nerves (phrenic), (3) the bellows (diaphragm and chest wall muscles), (4) the pleural space, and (5) the airways. Some situations in which hypoventilation may develop include (1) drug administration (barbiturates, diazepam, xylazine); (2) diseases of

the brainstem following infection (encephalitis), trauma, hemorrhage, or neoplasia; (3) diseases of the respiratory muscles, including botulism, trauma, or fatigue; (4) pleuritis and space-occupying lesions; and (5) choke and upper airway obstruction.

In patients suffering from hypoventilation, arterial oxygenation improves with oxygen administration (by increasing PIo_2), but the most efficacious mode of correcting the hypercapnia and consequent hypoxemia is by mechanical ventilation. Diffusion impairment occurs when time is inadequate for equilibration of alveolar oxygen tensions with pulmonary capillary oxygen tensions. Under normal resting conditions, equilibration of oxygen tensions occurs within 0.25 second, approximately one third of the contact time of the blood in the pulmonary circulation.[267] Some evidence suggests that in the exercising horse, the arterial hypoxemia that normally develops at high exercise intensities in part is caused by the decrease in time available for oxygen diffusion.[268,269] During rest, diffusion impairment is unlikely to occur. Arterial hypoxemia caused by diffusion impairment can be corrected by administration of supplemental oxygen.

V/ $\dot{Q}$ inequalities are the primary cause of arterial hypoxemia and occur when alveolar ventilation and pulmonary blood flow are mismatched despite the existence of several reflexes that normally tend to prevent this problem. For example, a fall in the $\dot{V}/\dot{Q}$ ratio causes alveolar hypoxia, which induces pulmonary vasoconstriction and decreases perfusion to that lung region. (But this reflex also increases pulmonary vascular resistance and thus the work of the right side of the heart.) A second reflex is hypocapnic bronchoconstriction. When the $\dot{V}/\dot{Q}$ ratio increases, regional ventilation of those lung units is reduced by smooth muscle constriction. $\dot{V}/\dot{Q}$ inequalities interfere with O_2 and CO_2 transfer so that hypoxemia and hypercapnia may ensue. Usually the consequent hypercapnia increases chemoreceptor drive and thus increases alveolar ventilation, which restores normocapnia. However, because of the shape of the oxyhemoglobin dissociation curve, the increase in oxygen tension in the normal alveoli caused by the hyperventilation does not increase the oxygen content of the blood coming significantly from these units. Several factors can exacerbate the hypoxemia of $\dot{V}/\dot{Q}$ inequalities, including hypoventilation (sedation) and decrements in cardiac output (mechanical ventilation with positive end-expiratory pressure). $\dot{V}/\dot{Q}$ inequalities respond to oxygen therapy, although this may lead to increases in arterial carbon dioxide tension by (1) a reduction of the chemoreceptor (hypoxic) drive, (2) an increase in $\dot{V}/\dot{Q}$ inequalities, and (3) a shift in the carboxyhemoglobin dissociation curve to the right, decreasing its affinity for carbon dioxide.[270] Mechanical ventilation may be indicated in severe $\dot{V}/\dot{Q}$ inequalities if hypercapnia is progressive.

Passage of blood through abnormal cardiovascular communications (atrial septal defects, ventricular septal defects, patent ductus arteriosus) or through pulmonary capillaries within the walls of atelectatic or fluid-filled alveoli causes shunts and consequent hypoxemia. Such defects may be considered as one extreme of $\dot{V}/\dot{Q}$ inequality ($\dot{V}/\dot{Q} = 0$) and are resistant to correction by oxygen therapy.[270] In shunts caused by pulmonary disease, mechanical ventilation and positive end-expiratory pressure increase end-expiratory lung volume and thus the alveolar surface area available for gas exchange. The incremental increase in end-expiratory lung volume also may help to redistribute the excessive extravascular lung water from the alveoli to the interstitium.

7.3.6 METABOLIC FUNCTIONS

The entire cardiac output passes through the pulmonary circulation, thus providing an ideal means by which 320
hormones and drugs may be metabolized to inactive compounds. Indeed, relative to the hepatic blood flow 321
(approximately 25% of the cardiac output), the contribution of the lungs to the total body clearance of drugs or xenobiotics may be significant. The lung contains hydrolytic enzymes that cleave peptides such as bradykinin and angiotensin I, thus serving to inactivate (bradykinin) or to bioactivate (angiotensin) compounds. The enzymatic activity responsible is concentrated within the caveolae of the pulmonary capillary endothelium or in pouchings in the plasma membranes of these cells.[271] Other pulmonary enzymes exist that are capable of cleaving phosphate groups from nucleotides (adenosine triphosphate, adenosine diphosphate, and adenosine monophosphate), of oxidizing steroid hormones (testosterone), of inactivating prostaglandins E and F, and of metabolizing biogenic amines such as 5-hydroxytryptamine, norepinephrine, and tyramine.[255,271,272]

7.3.7 DEFENSE AGAINST INFECTION

The sterile environment of the lung results from several mechanisms, including the mucociliary apparatus, which clears particulate debris from the lung at a rate of approximately 17 mm/min,[273] and vagally mediated reflexes, which serve to initiate coughing and concomitant bronchoconstriction. However, the predominant line of defense against noxious agents and bacteria is the alveolar macrophages of the distal airways and alveoli. Recent investigations have shown depression in alveolar macrophage function following exercise or long van rides.[274,275] Viral infections also depress macrophage function. Helping to maintain immunosurveillance and the sterile pulmonary environment are polymorphonuclear cells that respond to chemotactic stimuli and lymphocytes.

7.4 Disorders of the Lower Respiratory Tract

Disorders of the lower respiratory tract are common in horses of all ages. Presenting complaints vary with these disorders and may include exercise intolerance, cough, nasal discharge, fever, dyspnea, increased respiratory rate or effort, or generalized depression and inappetance. Careful clinical examination including auscultation while rebreathing often confirms the anatomic site of the problem. Ancillary diagnostic testing such as bronchoalveolar lavage, transtracheal wash, thoracic ultrasound, or thoracic radiography often are indicated to confirm a suspected diagnosis.

7.4.1 BACTERIAL PNEUMONIA

7.4.1.1 Causes

Normally the lungs contain only small numbers of bacteria (colony-forming units) that are considered to be transient contaminants in the process of being removed by clearance mechanisms.[276] When pulmonary defense mechanisms are overwhelmed, aspirated bacteria from the oropharynx may proliferate and cause pneumonia. The most common gram-positive bacteria involved are *Streptococcus zooepidemicus* (β-hemolytic), *Staphylococcus aureus,* and *Streptococcus pneumoniae* (α-hemolytic). The most frequent gram-negative isolates are *Pasteurella* and *Actinobacillus* spp., *Escherichia coli, Klebsiella pneumoniae,* and *Bordetella bronchiseptica.*[26,27,277–280] *Pseudomonas* is rarely a cause of equine pneumonia, and its isolation from tracheobronchial aspirates suggests environmental contamination of equipment (endoscope). *Nocardia* organisms also have been isolated from horses with pulmonary infections, but these are rare and appear to require significant derangements of the defense mechanisms.[281] The anaerobic bacteria most commonly isolated are *Bacteroides fragilis, Peptostreptococcus anaerobius,* and *Fusobacterium* spp. Polymicrobic infections are not uncommon in cases of equine pneumonia and may represent a synergy between aerobic/facultatively anaerobic and anaerobic bacteria. Mechanisms of synergy may involve protection from phagocytosis and intracellular killing, production of essential growth factors, and lowering of local oxygen concentrations.[278]

7.4.1.2 Pathogenesis

Bacterial pneumonia develops following viral infections, athletic events (races), trailor rides, and general anesthesia and also occurs in horses that are overcrowded, maintained on poor nutrition, or are exposed to inclement weather. Laryngeal and pharyngeal dysfunction also may predipose the horse to develop pneumonia by aspiration of oropharyngeal bacteria. Such predisposition occurs in horses (1) with primary neuropathies of the ninth and tenth cranial nerves (equine protozoal myeloencephalitis, botulism, *Streptococcus equi* infections, guttural pouch mycoses), (2) with primary myopathies of the pharyngeal, laryngeal, or esophageal musculature (vitamin E and selenium deficiency, megaesophagus), (3) following laryngeal surgery, or (4) with esophageal obstructions.

The pathogenic mechanisms described subsequently apply to the development of lung abscesses and pleuropneumonia.

Viral-induced modifications of respiratory tract defenses include (1) enhanced susceptibility to bacterial attachment and colonization following damage to the epithelial cells, (2) diminished mucociliary clearance and physical translocation of bacterial particles deposited on the bronchial ciliated epithelium, and (3) decreased surfactant levels and collapse of the airways because of viral destruction of alveolar type II cells.[282]
The ensuing anaerobic environment predisposes to macrophage dysfunction. In addition, the alveolar exudate 321
that accompanies viral pneumonitis may provide a nutrient medium for multiplication of aspirated bacteria. 322

Exercise, with aspiration of track debris and oropharyngeal secretions and with the development of exercise-induced pulmonary hemorrhage has been suggested as creating an ideal environment for bacterial growth and pneumonia.[283] An exercise-associated increase in bacterial contaminants of the lower respiratory tract has been demonstrated experimentally. Strenuously exercised horses exhibit a ten- and a 100-fold increase,

respectively, in the number of aerobic and anaerobic bacteria isolated from transtracheal aspirates relative to preexercise samples.[284] The bacterial contamination, along with exercise-associated increases in bronchoalveolar cortisol concentrations, decreased pulmonary alveolar macrophage viability, and impaired phagocytic function, enable bacteria to proliferate and cause pneumonia.[274,275,283,285,286]

Transportation remains one of the most common causes of pneumonia and pleuropneumonia in the horse because physically restraining the head of the horse and preventing postural drainage enhances bacterial colonization of the lower respiratory tract.[283,287] Inflammation and increased numbers of bacteria are found in the transtracheal aspirates of horses within 6 to 12 hours of confinement with the head elevated.[288] Another hypothesis is that dehydration, associated with reduced fluid consumption before or during transportation, reduces mucociliary clearance and contributes to bacterial proliferation. Neither the prophylactic administration of antibiotics nor the intermittent release from the confined head posture reliably reduces tracheal bacterial numbers or prevents the accumulation of purulent tracheobronchial secretions in horses confined with their heads elevated.[288,289]

Horses undergoing general anesthesia may develop pneumonia when endotracheal intubation introduces oropharyngeal contaminants to the lower respiratory tract. Anesthesia may compromise mucociliary clearance, and compression atelectasis and vascular congestion may cause regional ischemia and necrosis of lung regions, providing local conditions suitable for bacterial multiplication.[283]

7.4.1.3 Clinical Signs

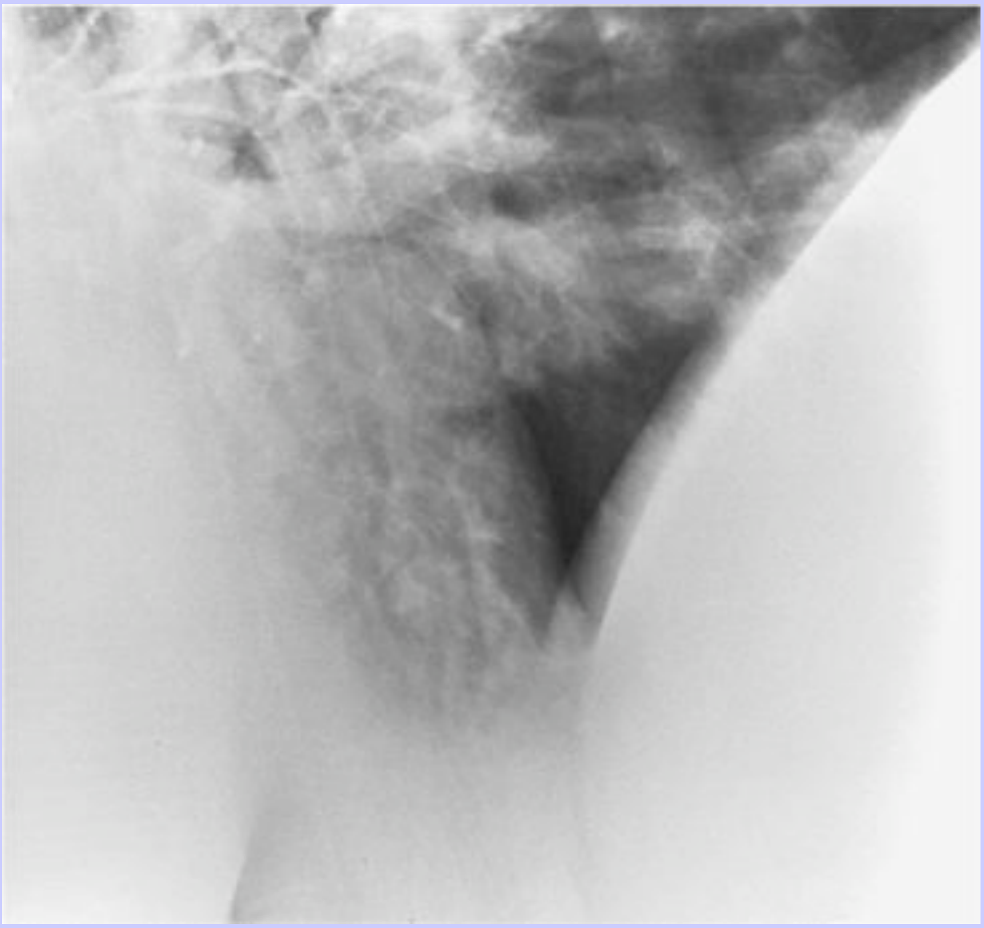
In early cases, clinical signs may not be obvious, being limited to a gurgling sound of exudates in the trachea, fever, or depression. As the pneumonia progresses, horses may exhibit intermittent fever, tachypnea or respiratory distress, nasal discharge, coughing, inappetence, exercise intolerance, and weight loss. Nasal discharge is usually mucopurulent but may be hemorrhagic in some cases.[278] Auscultation of the thorax reveals increased harsh breath sounds dorsally, crackles, and wheezes and dullness of respiratory sounds ventrally. Manipulation of the trachea or larynx may induce a cough. Halitosis and a foul-smelling nasal discharge suggest an anaerobic infection. Submandibular lymphadenopathy may be apparent in aspiration pneumonia associated with strangles or with viral infections.

7.4.1.4 Diagnosis

Clinical signs and history aid in diagnosis. Clinical pathologic data supportive of a bacterial pneumonia include a leukocytosis and an absolute neutrophilia, with or without a left shift. Neutropenia also may be evident if gram-negative organisms are involved. A hyperfibrinogenemia (>500 mg/dl), hyperglobulinemia, hypoalbuminemia, and anemia of chronic inflammation are compatible with the diagnosis of chronic bacterial pneumonia. Endoscopic evaluation of the upper respiratory tract may demonstrate a defect in the laryngeal pharyngeal function if this is the inciting cause. One may observe a mucopurulent exudate with or without traces of blood by endoscopy in the lower respiratory tract. Thoracic radiographs demonstrate a radiopacity in the anteroventral thorax and a loss of clarity in the lung fields caudal to the heart. Air bronchograms occasionally are found in the adult horse with bacterial pneumonia (Figure 7-13). Ultrasound may demonstrate consolidation of ventral lung lobes and extension of the pneumonia to the pleural surfaces. Tracheobronchial aspirates yield degenerative neutrophils, damaged epithelial cells, and microorganisms. The presence of 322
squamous epithelial cells supports a diagnosis of aspiration pneumonia, provided that the tracheal catheter was 323

not misplaced in the pharynx during sampling. The clinician should perform aerobic and anaerobic cultures on the tracheal aspirates.

Figure 7-13 Two-year-old Thoroughbred with pneumonia. A patchy area of pulmonary consolidation is notable in the ventral dependent portion of the lung silhouetting the heart and diaphragm. (Courtesy D.S. Biller, Manhatten, Kansas, 1991.)



7.4.1.5

Treatment

The clinician should direct treatment at the causative organism, but in the absence of culture sensitivity results, one should administer broad-spectrum antimicrobials. Appropriate therapy might include intravenous aqueous sodium or potassium penicillin and an aminoglycoside or third-generation cephalosporin (Table 7-2). The aminoglycosides are efficacious against most gram-negative aerobes, but lack efficacy against anaerobes. However, metronidazole is effective against most anaerobes, including the penicillin-resistant *Bacteroides fragilis* and routinely is included in the treatment protocol. Depending on the culture sensitivity results, one also may administer potentiated sulfonamides. The clinician should use aminoglycosides judiciously in

animals that have renal compromise or are dehydrated. (See the section on treatment for parapneumonic effusions.)

TABLE 7-2 Antimicrobials Commonly Used to Treat Respiratory Conditions

ANTIMICROBIAL	DOSAGE*
Amikacin	16–18 mg/kg, IV, s.i.d.
Ampicillin sodium	11–22 mg/kg, IV or IM, t.i.d. or q.i.d.
Ceftiofur	2.2 mg/kg, IV or IM, b.i.d.
Chloramphenicol	50 mg/kg, PO, q.i.d.
Enrofloxacin	7.5 mg/kg, PO or IV, s.i.d.
Gentamicin	6.6 mg/kg, IV or IM, s.i.d.
Metronidazole	15–25 mg/kg, PO, t.i.d. or q.i.d.
Oxytetracycline	5.0 mg/kg, IV, b.i.d.
Potassium Penicillin G	22,000 IU/kg, IV, q.i.d.
Procaine Penicillin G	22,000 IU/kg, IM, b.i.d.
Rifampin	5–10 mg/kg, PO, b.i.d.
Sodium Penicillin G	22,000 IU/kg, IV, q.i.d.
Trimethoprim-sulfonamide	15–20 mg/kg, PO or IV, b.i.d.

* b.i.d., Twice daily; IM, intramuscularly; IV, intravenously; PO, orally; q.i.d., 4 times daily; s.i.d., once daily; t.i.d., 3 times daily.

With gram-negative infections and the potential for endotoxemia, small doses of flunixin meglumine (0.25 mg/kg 3 times daily) may be given to inhibit arachidonic acid metabolism. Other treatment modalities that have been advocated include nebulization of mucolytics, the use of bronchodilators and expectorants, and prophylactic measures against laminitis. The goal of supportive care should be to minimize stress and ensure adequate ventilation and hydration. Ideally, horses should be bedded on paper or on other materials free of dusts or molds and should be fed forages of excellent quality. One should also direct attention to correcting the primary cause of the pneumonia. Depending on the chronicity of the pneumonia, one should note clinical improvement in 48 to 72 hours. The prognosis can be excellent if the pneumonia is treated aggressively, but the clinician should forewarn the owner of potential complications (see the following discussion). The clinician should administer treatment for 2 to 6 weeks depending on the extent of the pneumonia and the underlying inciting cause. (See the section on treatment for parapneumonic effusions.)

Preventive measures that help deter the development of pneumonia include (1) adequate immunization protocols with vaccination against equine influenza virus, EHV1, and EHV2, every 4 to 6 months (in the performance horse); (2) the minimization of stresses such as long van rides in which the head is restrained constantly; and (3) the use of management or husbandry methods that minimize dust or noxious gas accumulations within the stall, prevent exposure to inclement weather, and provide adequate nutrition for the horse.

7.4.2 LUNG ABSCESSES

7.4.2.1 Causes

In foals less than 6 months of age, *Rhodococcus equi* and *Streptococcus zooepidemicus* are the most common bacterial isolates recovered.[290] In adult horses, *Streptococcus* and *Actinobacillus* species are the most gram-positive and gram-negative organisms implicated in the development of pulmonary abscesses.[290–292] This discussion predominantly addresses lung abscesses in the adult horse.

7.4.2.2 Pathophysiology

Lung abscesses may develop as a consequence of inhaling bacterial organisms resident to the oropharynx or contaminating the environment *(Rhodococcus equi)*. The abscess may develop as a consequence of a focal pneumonia or may be a component of pleuropneumonia complex. Racehorses may be at an increased risk for developing lung abscesses when bacteria proliferate in the blood in the airways and alveoli following episodes of EIPH. The regional location of lung abscesses in these cases supports this hypothesis.[292]

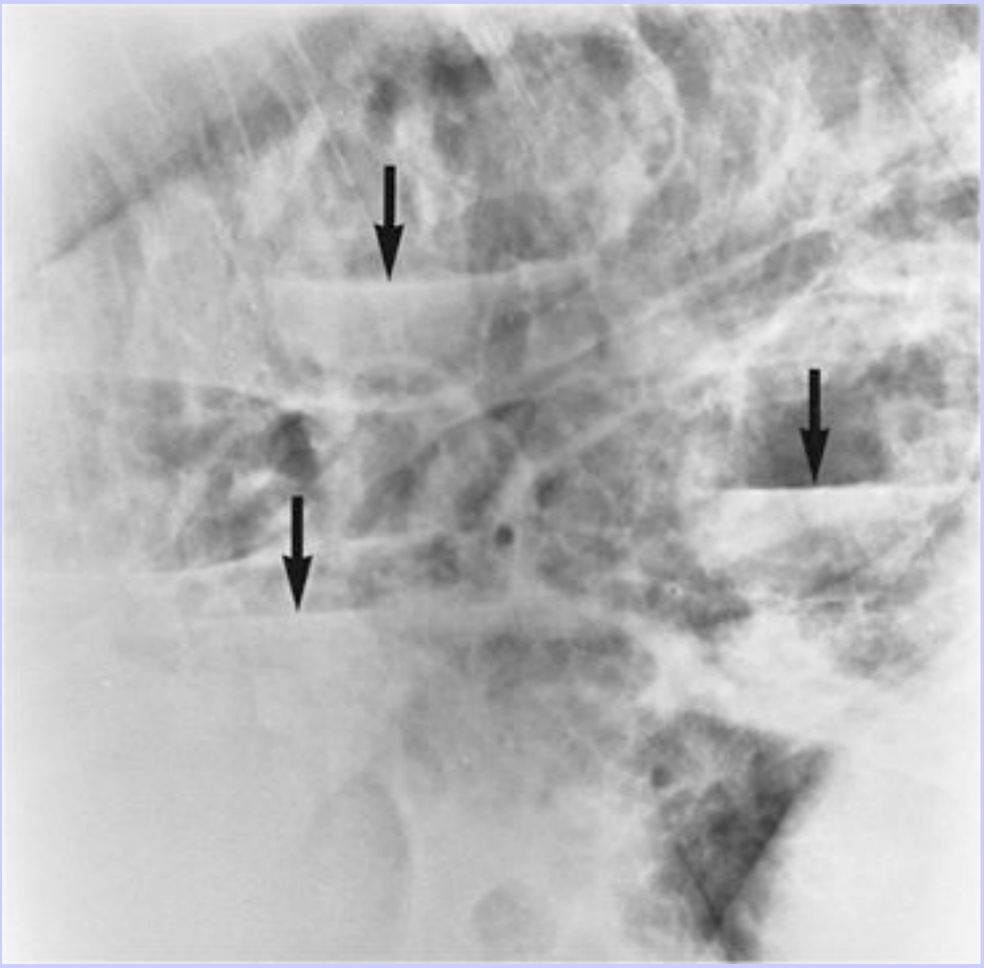
7.4.2.3 Clinical Signs

Clinical signs may vary, but most horses have periods of pyrexia, inappetance, lethargy, mild tachycardia, and respiratory-related signs ranging from tachypnea to distress.[291,292] Other signs that may be evident include cough, purulent nasal discharge, thoracic pain, epistaxis, and halitosis.

7.4.2.4 Diagnosis

The adult horse may have a history of transport, strenuous exercise, surgery, prior pneumonia, or 323
administration of medications. In most cases, evidence of an infection is found on the CBC and serum 324
chemistry panel: a mature neutrophila, hyperfibrinogenemia, hyperglobulinemia, and anemia. Radiography and ultrasound are useful imaging modalities, and one may use them concurrently to detect lung abscesses (Figures 7-14 and 7-15). Pulmonary abscesses appear on ultrasonography as encapsulated cavitated areas filled with fluid or echogenic (white) material. Cardiac structures or air-filled lung may overlie an abscess, obscuring its detection. In one study, two thirds of the abscesses were located in the caudodorsal lung field, whereas the remaining abscesses were located in the caudoventral region.[292]

Figure 7-14 Nine-year-old saddle horse. Multiple cavitating pulmonary abscesses are present within the lungs. Arrows indicate air-fluid interfaces within the abscesses. (Courtesy D.S. Biller, Manhatten, Kansas, 1991.)



Transtracheal aspirates or percutaneous aspirates of lung abscesses adhered to the body wall may help the clinician decide the choice of antimicrobials. One should culture isolates under aerobic and anaerobic conditions.

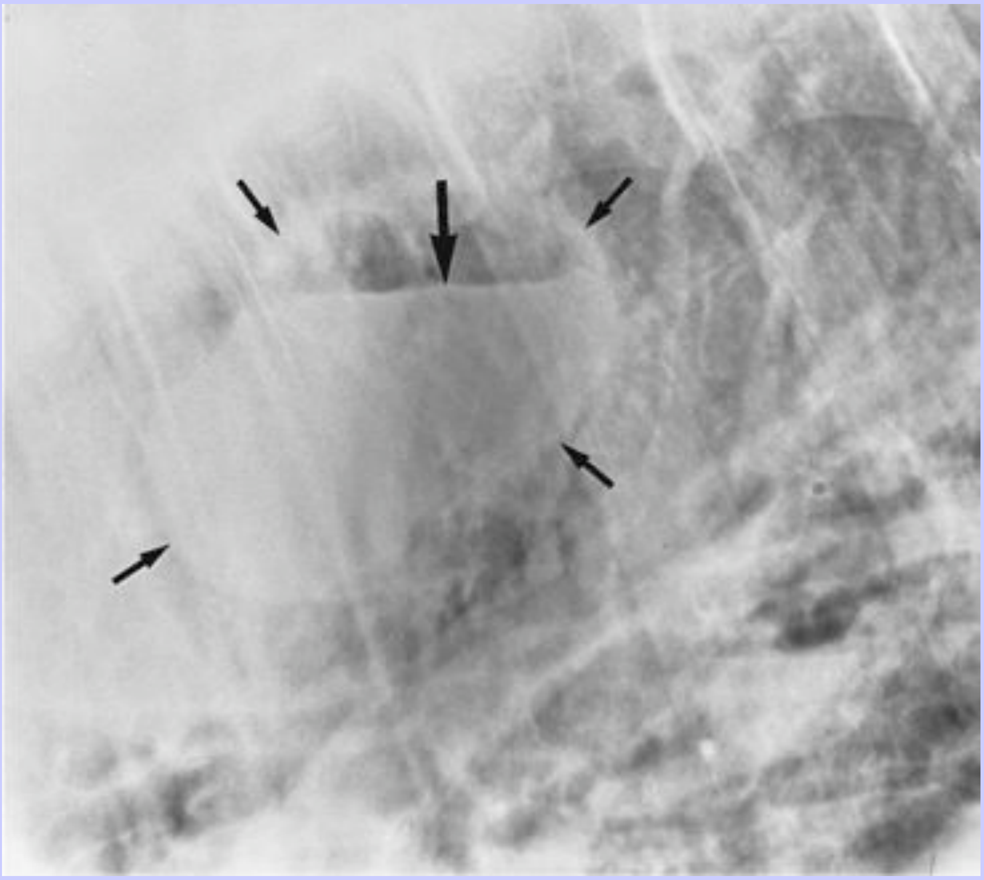
7.4.2.5

Treatment

Long-term antimicrobial therapy (8 to 10 weeks) along with prolonged periods of rest (5 to 6 months) before resuming strenuous exercise is recommended. (See the section on treatment for parapneumonic effusions for specific antimicrobial recommendations.) In human beings receiving antimicrobial treatment for pulmonary absceses, an 80% reduction in the size of abscess cavities less than 3 cm in diameter usually occurs within 1

month of appropriate therapy.[293] Furthermore, 70% of cavitary lesions in human cases of lung abscessation resolve completely by 3 months.[294] For lung abscesses unresponsive to therapy, the clinician should consider drainage via a thoracotomy or thoracoscopy.[295]

Figure 7-15 A large air-capped pulmonary abscess. Small arrows indicate an abscess; large arrow indicates the air-fluid interface. (Courtesy D.S. Biller, Manhatten, Kansas, 1991.)



Prognosis for resumption of athleticism is good if treatment is initiated early. In one study, 23 of 25 Standardbreds and 13 of 20 Thoroughbreds raced after the diagnosis and treatment of a lung abscess with no significant effect on race performance.[292]

7.4.3 PARAPNEUMONIC EFFUSIONS AND SEPTIC PLEURITIS

7.4.3.1 Causes

Between two thirds and three quarters of cases of septic pleuritis arise as an extension of pneumonia or pulmonary abscessation.[296–298] Septic pleuritis also may occur in cases of thoracic trauma, esophageal

rupture, or penetration of the esophagus or stomach by a foreign body.[283,299–301] The aerobic or facultatively anaerobic organisms most often isolated from horses with pleuropneumonia are bacterial species that normally reside in the oropharyngeal cavities: *Streptococcus* spp., *Pasteurella* and *Actinobacillus* spp., *Escherichia coli,* and *Enterobacter* spp. Anaerobic organisms frequently isolated include *Bacteroides* spp., *Peptostreptococcus* spp., *Fusobacterium* spp., and *Clostridium* spp.[301–303]

7.4.3.2 Epidemiology

Risk factors for the development of pleuropneumonia are the same as those associated with pneumonia (see 324
the previous discussion) and include long-distance transport, strenuous exercise, viral respiratory tract disease, 325
surgery, dysphagia, general anesthesia, and systemic illness (enteritis). These conditions may enhance aspiration of oropharyngeal organisms or may impair clearance of such organisms.[283,297,304]

7.4.3.3 Pathogenesis

The causative factors of equine pleuropneumonia are those that suppress the pulmonary defense mechanisms and allow bacterial contamination of the lower respiratory tract to progress to pneumonia or abscess formation. The subsequent extension of the infectious process into the pleural space causes pleuritis. The distribution of the pulmonary lesions—cranioventral with the right cranial and middle lung lobes more severely afflicted—is consistent with inhalation or aspiration of bacteria rather than infection from a hematogenous spread. Fluid accumulates within the pleural cavity as the parenchymal inflammation increases the permeability of the capillaries in the overlying visceral pleura, causing an outpouring of protein and cells. Bacteria also may invade the pleural fluid.

7.4.3.4 Clinical Signs

Depending on the chronicity of the disease, the clinical signs may vary and may be confused with signs of colic or rhabdomyolysis. In the acute stages, horses are febrile and lethargic, have a slight nasal discharge, and exhibit a guarded cough, shallow breathing pattern, and painful, stilted gait.[303] The right hemithorax is affected more often than the left, presumably because of the more direct route of the right main stem bronchus.[283] Thoracic auscultation may be abnormal as evidenced by pleural friction rubs and ventral dullness. In severe acute cases the horse may exhibit nostril flaring; tachycardia; jugular pulsations; toxic mucous membranes; a guarded soft, moist cough; and a serosanguinous fetid nasal discharge. In chronic cases of pleuropneumonia (duration greater than 2 weeks), horses may have bouts of intermittent fever and exhibit weight loss and substernal and limb edema.

7.4.3.5 Diagnosis

Diagnosis is based on historical information, clinical examination, imaging results, and microbiologic and cytologic analysis of tracheal and pleural fluid aspirates.

On auscultation of the thorax, one may hear vesicular sounds only dorsally, with an absence of lung sounds ventrally. One may hear bronchial or tracheal sounds if lung consolidation exists. Cardiac sounds radiate over a wider area of the lung field than normal, a finding distinct from clinical cases of pericarditis. On percussion of the chest, the clinician may elicit a painful response (pleurodynia) and detect an area of dullness or decreased resonance ventrally.

Laboratory assessment may demonstrate normal or toxemic leukogram and chemistry findings in the acute cases, whereas in chronic cases, one may find anemia, neutrophilia, hyperfibrinogenemia, and hyperproteinemia.

Ultrasound is the diagnostic technique of choice in cases of pleuropneumonia or pleural effusion. Using a 3.5- to 5-MHz transducer (sector scanner or linear probe), one can detect free or loculated fluid, pleural thickening, pulmonary and mediastinal abscesses, pulmonary consolidation, inundation of airways with fluid, fibrinous adhesions, and concurrent pericarditis. Pleural fluid may displace the lungs axially and dorsally. The fluid may appear anechoic or hypoechoic depending on the relative cellularity.[303] Free gas echoes within the pleural fluid may reflect (1) the presence of anaerobic organisms,[33] (2) the presence of air introduced during a thoracocentesis, or (3) the presence of air introduced by a bronchopleural fistula.

Ultrasonography enables accurate placement of the catheter during thoracocentesis and ensures productive yields during placement of a chest drain (Figures 7-16 to 7-18). Ultrasound examination fails to demonstrate deep parenchymal lesions if the overlying lung is normally aerated.

Thoracic radiography also remains a useful technique for evaluating horses with pleuropneumonia, permitting detection of a pneumothorax or an abscess located deep in aerated lung tissue. Pneumothorax may develop following transtracheal aspiration, thoracocentesis, thoracic drainage, or pleuroscopy. Pneumothorax also may develop as a sequela to gas-producing organisms in the pleural cavity or to air leaks from bronchopleural 325
fistulae.[283] Although radiographs may detect pulmonary abscesses, they may fail to detect lesions obscured by 326
the cardiac silhouette.

The echogenic *(white)* tortuous fibrin strand is attached to the parietal pleura of the diaphragm. *V,* Ventral; *D,* dorsal; *arrow,* diaphragm. (Courtesy D.S. Biller, Manhatten, Kansas, 1991.)

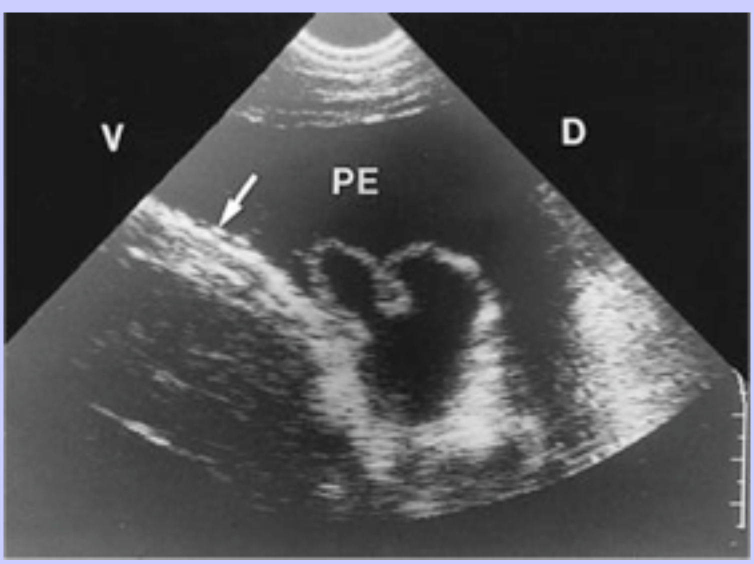


Figure 7-17 Normal thoracic ultrasound demonstrates a highly echogenic interface *(arrows)* between the chest wall and normal lung. A reverberation artifact is notable deep to the chest wall–lung interface. (Courtesy D.S. Biller, Manhatten, Kansas, 1991.)

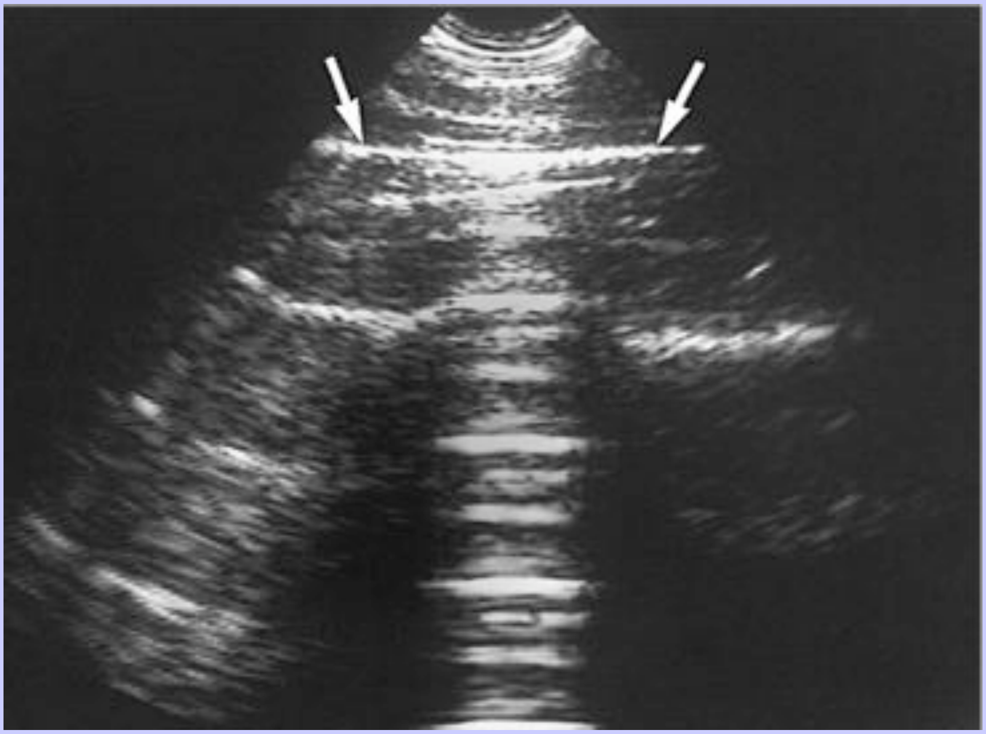
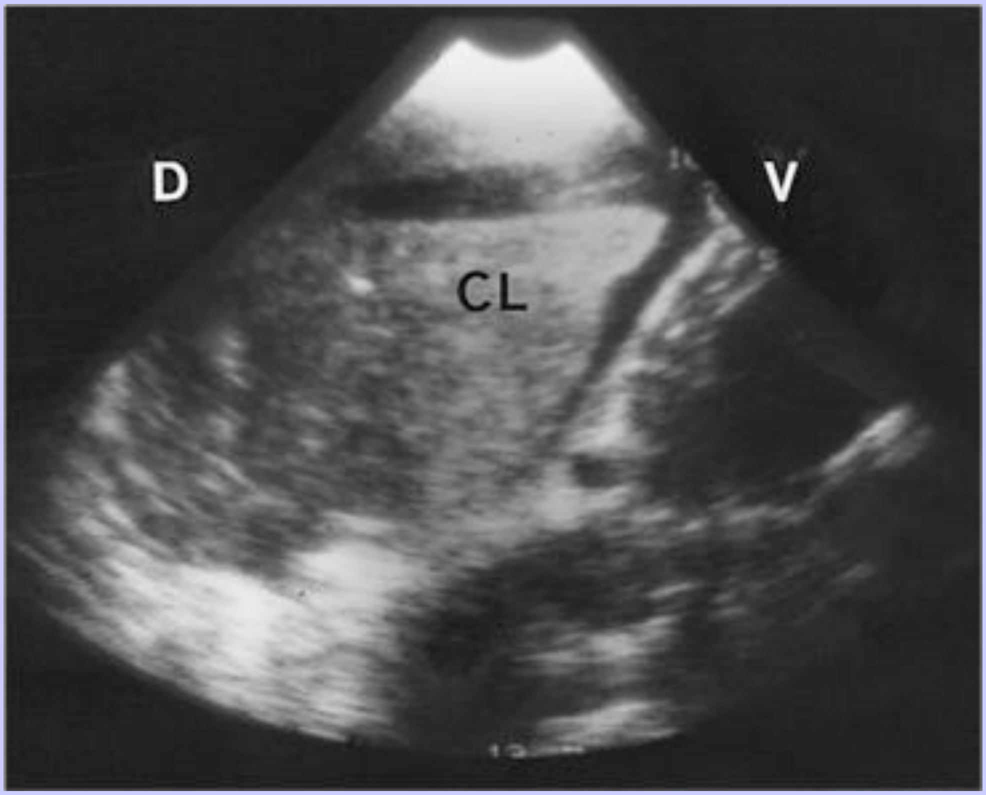


Thoracocentesis of both sides of the chest is indicated if one notes fluid bilaterally. Not only is thoracocentesis diagnostic and prognostic, it may be a therapeutic life-saving procedure in horses with severe respiratory distress.[305] In healthy horses the fenestrated caudal mediastinium allows communication of the fluid between the two sides of the chest. In horses with pleuropneumonia, fibrin may close mediastinal fenestrations, allowing for differences to develop in the pleural fluid of the two hemithoraces. The clinician should submit fluid for cytologic examination and for aerobic and anaerobic culture. Pleural fluid in healthy horses contains fewer than 10,000 cells per μl, approximately 60% of which are neutrophils, and has a total protein of less than 2.5 g/dl. In cases of pleuropneumonia, pleural fluid white blood cell counts and protein are elevated and glucose levels may be low (<40 mg/dl). The fluid may have a foul odor if anaerobes are contributing to the infection, but the absence of an odor should not preclude the possibility of an anaerobic component.

Figure 7-18 Ultrasound of ventrally consolidated lung *(CL)* surrounded by a small amount of pleural effusion. *V,* Ventral; *D,* dorsal. (Courtesy D.S. Biller, Manhatten, Kansas, 1991.)



The clinician always should obtain a tracheobronchial aspirate to recover the inciting bacterial agents and to examine tracheobronchial secretions cytologically (Gram stain, cell types). One should submit aspirates for aerobic and anaerobic culture and a Gram staining to provide guidance on antimicrobial selection. During the course of the disease, one may obtain multiple tracheobronchial aspirates to identify new or resistant bacterial organisms.

One can use thoracoscopy, performed in standing sedated horses or in horses under general anesthesia, in acute and chronic cases of pleuropneumonia (1) for guided placement of drains into abscesses and loculated pleural effusions; (2) for assessment of the extend and progression of pleural disease; and (3) for the evaluation of therapeutic responses and the efficacy of pleural lavage/drainage.[306]

7.4.3.6

Treatment

Treatment aims at (1) removing excessive pleural fluid; (2) administering systemic antimicrobials to inhibit bacterial growth; (3) providing antiinflammatory and analgesic drugs that deter the development of secondary complications; and (4) providing supportive care.

Under ultrasound guidance, one can remove pleural fluid aseptically through the seventh or eighth intercostal spaces at a locale dorsal to the costochondral junction using a 24-32 French chest tube. One may remove as much as 30 to 50 L. If blood discoloration of the pleural fluid is caused by the underlying disease, the fluid remains blood-tinged throughout the drainage.[305]

The clinician should place indwelling chest tubes (1) if large volumes of foul-smelling fluid with microorganisms are obtained; (2) if the pleural fluid has a pH less than 7.2 or a glucose concentration less than 40 mg/dl; or (3) if the horse responds poorly to intermittent drainage.[298–305] One should avoid the rapid removal of large volumes of fluid from the chest to guard against the development of hypovolemia. To the end of the indwelling chest tube one should attach a Heimlich valve or a nonlubricated condom with its tip snipped off. Complications of chest tube placement include pneumothorax; lung laceration; hemothorax; cardiac arrhythmias; bowel, liver or heart puncture; and localized swelling.[305] 326

327

Appropriate antimicrobial therapy is based on the results of the culture and sensitivity. Pending microbiologic test results, one should administer broad-spectrum intravenous antibiotics in most cases of pleuropneumonia because the infections are polymicrobic. Penicillin is one of the drugs of choice, for it is efficacious against *Streptococcus* spp., *Staphylococcus* spp., and many anaerobes. Metronidazole is added routinely to the penicillin to broaden bactericidal activity against anaerobes, especially *Bacteroides fragilis*. Aminoglycosides lack efficacy against anaerobic bacteria and have poor penetration into respiratory tract secretions but still are administered with penicillin. Third-generation cephalosporins such as ceftiofur sodium, with activity against gram-negative aerobes and facultative anaerobes, showed excellent efficacy in the treatment of spontaneous clinical and posttransport pneumonia associated with *Streptococcus zooepidemicus, Actinobacillus* spp., and *Pasteurella* spp.[307]

Depending on the clinical response of the horse, 10 to 14 days after the onset of initial therapy, the clinician usually replaces parenteral antimicrobials with oral antibiotics. Chloramphenicol, a bacteriostatic drug, has excellent broad-spectrum activity against gram-negative, gram-positive, and anaerobic bacteria and can be given orally. (One must use caution when handling the drug.) Enrofloxacin, a fluoroquinolone, has excellent antibacterial action against aerobic gram-negative bacteria, many gram-positive bacteria, and mycoplasma bacteria but has limited activity against *Streptococcus* spp. and anaerobes.[308] Concentrations of the enrofloxacin in lung tissue are similar to those in serum.[309] Erythromycin and rifampin attain good concentrations in the lung and pleural fluid and within phagocytic cells, but rifampin is expensive and erythromycin may induce a fatal colitis, precluding their use in adult horses.[310]

Antimicrobial therapy should continue for 2 to 4 months until the horse is gaining weight, hematologic and serum chemistry values have normalized, and no evidence of respiratory tract disease exists. One should implement limited exercise (hand walking) and avoidance of stress. One should reevaluate refractory cases using the techniques of ultrasonography, thoracocentesis, or transtracheal aspiration to determine if drug resistance has developed, if additional pathogens are involved, or if untoward sequelae have occurred (see the following discussion).

In refractory cases, drainage of pulmonary or mediastinal abscesses or mechanical debridement of fibrinous material (decortication) may become necessary. One should consider initially attempting drainage using a large-bore chest tube (24F) directed through the chest wall and then the capsular wall of the abscess followed by suction of the abscess contents. Lavage of the contents of the abscess may improve removal of the purulent material. One should take care to prevent spillage of the contents into the pleural cavity. For removal of

fibrinopurulent material or necrotic lung segments, a standing thoracotomy may provide necessary access.[311] After removing accessible exudates and fibrin manually, one lavages the chest cavity with a warm 1% Betadine solution, packs it with a large lap sponge, and covers it with a self-adhering dressing and pad. One must lavage the pleural cavity daily. Fistulae formation is a common sequela in these clinical cases, but this does not preclude horses from returning to racing or breeding careers.

Nonsteroidal antiinflammatory drugs (flunixin meglumin, 0.25 to 0.50 mg/kg intravenously 2 to 3 times daily) provide analgesia, increase appetite, increase the comfort of the horse, and decrease the inflammatory response.

Many horses with pleuropneumonia benefit from the administration of intravenous fluids for the first 48 to 72 hours, until the horse is comfortable enough to resume drinking and the danger of endotoxemia has lessened. Nasal insufflation of oxygen (10 to 15 L/min) may be indicated if the horse is hypoxemic or in respiratory distress. One may achieve bronchodilation using inhaled or nebulized albuterol (600 to 720 μg 3 to 4 times daily). Because gram-negative organisms are often involved in pleuropneumonia cases, one should implement prophylactic measures against laminitis.

7.4.3.7 Prognosis

A favorable response most often relates to early identification and aggressive treatment of pleuropneumonia. Survival rates[297,312] of horses treated for acute pleuropneumonia range from 49% to 98%. Prognosis deteriorates with increased duration of illness because of involvement of anaerobic bacteria and the development of complicating factors such as pleural adhesions, pulmonary necrosis, cranial mediastinal abscesses, bronchopleural fistulae, constrictive pericarditis, and laminitis.[312,384] In a recent study, 61% of Thoroughbreds treated for pleuropneumonia raced after recovery, with 56% winning at least one race.[313]

7.4.3.8 Complications

Long-term medical treatment of pleuropneumonia may induce complications such as venous phlebitis or thrombosis (from intravenous catheter placement), cellulitis or pneumothorax following thoracocentesis, diarrhea resulting from antimicrobial and antiinflammatory therapy or endotoxemia, and laminitis. With minor changes in the therapeutic approaches, many of these complications resolve and do not impede the eventual return to health of the horse. The more complicated sequelae of infectious pleuropneumonia have been 327
described in detail by Byars, Dainis, Seltzer, et al.[314] and Byars and Becht.[315] In a survey of 153 horses 328
brought to their veterinary hospital over a 4-year period with pleuropneumonia, they detailed the development of cranial thoracic masses (7.2%), bronchopleural fistulae (6.5%), pericarditis (2.6%), and laminitis (1.3%).

One should suspect cranial thoracic masses when horses exhibit tachycardia, jugular distention, forelimb extension (pointing), and caudal displacement of the heart. One can confirm the presence of empyema, loculations, or encapsulated abscesses cranial to the heart by ultrasonography. In most cases, medical therapy is effective at reducing the abscess, and thus one should elect this conservative approach initially. Additional therapeutic modalities include the administration of a diuretic (furosemide) and a chronotropic agent (digitalis) to improve cardiac performance. However, refractory cases may require ultrasound-guided drainage of the abscess performed under short-term anesthesia (xylazine-ketamine combination).

Bronchopleural fistulae develop when necrotic pulmonary tissue sloughs, providing a direct communication of the airways with the pleural cavity. One confirms diagnosis by visualization of the airways following

pleuroscopy or by the intratracheal appearance of contrast media injected into the pleural cavity. Bronchopleural fistulae may close eventually as the pulmonary tissue adheres to the chest wall or as the airways close. Thoracoscopic-guided closure of the bronchopleural fistualae may be necessary in long-standing cases.

7.4.4 PLEURAL EFFUSION

7.4.4.1 Causes

Accumulation of fluid within the pleural space most often results from imbalances in Starling's law of fluid fluxes. As described previously, pleural effusions in the horse most commonly occur with bacterial pneumonia or lung abscesses.[316] (See the section on treatment for parapneumonic effusions.) Pleural effusions also may accompany a number of thoracic neoplasms such as fibrosarcoma, gastric squamous cell carcinoma, hepatoblastoma, hemangiosarcoma, melanoma, mesothelioma, and metastatic mammary or ovarian adenocarcinoma but most commonly are associated with lymphoma.[317–326] Pleural effusion also develops in a number of other conditions, including thoracic trauma; pericarditis; peritonitis; viral, mycoplasmal, and fungal infections; congestive heart failure; liver disease; diaphragmatic herniation; hypoproteinemia; equine infectious anemia; pulmonary granulomata; and damage of the thoracic duct.[298,327–329]

7.4.4.2 Pathogenesis

Pleural fluid is really the interstitial fluid of the parietal pleura. A pressure gradient driving its formation exists because the parietal pleura is supplied by the systemic circulation and because the pressure of the pleural space is more negative than that of the subpleural interstitium.[330] Pleural liquid and protein exit the pleural space via the parietal pleural stomata. Fluid production in the pleural space increases if any of the following occur: (1) an elevation of the hydrostatic pressure gradient (congestive heart failure, portal hypertension); (2) a decrease in the colloid osmotic pressures (hypoproteinemia); (3) an increased permeability of the capillary vessels (infection, malignancy, inflammation); or (4) a decreased removal of fluid because of impaired lymphatic drainage (neoplasia) or a decrease in the pleural space (atelectasis).[331] Excessive amounts of peritoneal fluid may accumulate in the pleural cavity as the fluid moves through diaphragmatic defects or through diaphragmatic lymphatics.[330]

7.4.4.3 Diagnosis

A physical and rectal examination, CBC and chemistry panel, cardiac evaluation, thoracic and abdominal ultrasound, and abdominal centesis may be helpful in determining the cause of the pleural effusion. When one suspects infectious agents, one should perform a transtracheal aspirate. One also should obtain a Coggins test and titers against *Coccidioides immitis, Cryptococcus neoformans,* and *Mycoplasma felis,* depending on the nature of the effusion and the geographic location of the affected horse.

Cytologic and microbiologic evaluation of the pleural fluid may help to identify neoplastic cells or fungal elements. Transudates, fluid with a total protein less than 2.5 g/dl, and few cells usually are associated with congestive heart failure, liver fibrosis, hypoalbuminemia, or early neoplastic processes. Modified transudates have low nucleated cell counts (<10,000 cells/μl) and moderate to high protein levels (>2.5 g/dl) and can be found in many disorders including neoplasia. Exudates have nucleated cell counts exceeding 10,000 cells/μl

and total protein levels greater than 3.0 g/dl and are found in infections and intraabdominal diseases.[316] One can distinguish septic effusions from nonseptic effusions by biochemical analysis of pleural fluid aspirates. For example, fluid that has a pH less than 7.2, a glucose concentration less 40 mg/dl, and a lactate dehydrogenase concentration greater than 1000 IU/L has been suggested to indicate septic effusions. Chylous effusions (which are milky white to pale pink) have triglyceride concentrations exceeding that of simultaneously measured serum.[316]

7.4.4.4 Treatment

Treatment aims at the primary cause, but neoplastic conditions and pleural effusions associated with an end-stage organ failure carry a poor prognosis. Therapeutic thoracocentesis is indicated in malignant effusions when horses are experiencing breathing difficulties. Chest tube drainage and chemical pleurodesis or 328
thoracoscopy with talc poudrage may be one treatment option. The clinician should consider these procedures 329
if (1) significant improvement in the status of the horse occurs with pleural fluid evacuation and (2) reexpansion of the lung is achieved once fluid is removed. Adapting protocols from human medicine[332] (as successful management of malignant effusions in equine medicine has not been described) requires that the horse first be sedated. Then one administers a sclerosing agent in 100 to 500 ml of sterile solution through a chest tube. One clamps the tube for 1 hour before reconnecting it to continuous suction. One sclerosing agent that has been used is doxycyline (500 mg in 50 to 100 ml saline for human beings).

Poudrage is the most widely used method of instilling talc into the pleural space and usually is performed under thoracosopic guidance. Before spraying the talc over the visceral pleura, one should remove all pleural fluid: complete collapse aids in distributing the talc. In human medicine, one usually instills 5 g (8 to 12 ml) evenly over the pleural surface, places a chest tube, and applies progressive suction until the amount of fluid aspirated per day is less than 100 ml.[332]

7.4.5 FUNGAL PNEUMONIA

7.4.5.1 Causes

Primary fungal pathogens causing respiratory tract disease in the horse include *Blastomyces dermatitidis, Coccidioides immitis, Cryptococcus neoformans,* and *Histoplasma capsulatum*.

B. dermatitidis is a thermally dimorphic fungus: it exists as a mold at room temperature and as a budding, round yeastlike cell when cultured at 37° C or when replicating in the host. As a soil saprophyte, *B. dermatitidis* can be found near decomposed vegetation or rotting wood.[333] Although respiratory tract disease caused by this organism is rare in the horse, inhalation of the spores may cause a pyogranulomatous pneumonia.[334]

Coccidioides immitis, a soil saprophyte, is also dimorphic, existing as a mold on most culture media and as a nonbudding spherical form in the host tissue. Fungal pneumonia and pleuritis result from inhalation of wind-borne arthrospores. Lymphohematogenous dissemination of the organisms may lead to the development of lesions in the bones, skin, and meninges.[335]

Cryptococcus neoformans is a yeastlike fungus that reproduces by budding, forming cells 4 to 7 µm in diameter. The organism has a predilection for the respiratory tract and for the central nervous system. The

proposed route of infection is via inhalation with secondary hematogenous spread to the central nervous system. When *C. neoformans* replicates within the host or on culture media, the organism forms a large polysaccharide capsule that appears as a clear halo around the cell when organisms are stained with India ink.[336] The capsule is antiphagocytic and immunosuppressive: secretion of capsular antigens into the body fluids binds opsonizing antibody before it reaches the organism. Based on the capsular antigens, two varieties of *C. neoformans* exist: *C. neoformans* var. *neoformans* (serotypes A and D) and *C. neoformans* var. *gatti* (serotypes B and C).

Histoplasma capsulatum is a dimorphic fungus found in the soil and on decaying vegetation. Heavy concentrations of the organism accumulate in soils containing bat or bird feces. The organism is highly infectious as an airborne spore (microconidia) but is of low virulence when it converts to the yeast phase (2 to 4 μm) in the host.[336] Systemic histoplasmosis is uncommon in proportion to the equine population exposed: the horse seems particularly resistant to infection.[337] The propose route of infection is via inhalation or ingestion of the microconidia. Because the organism parasitizes mononuclear phagocytes and has an affinity for the reticuloendothelial system, it may disseminate to the liver, spleen, lymph nodes, and bone marrow.[338]

Opportunists such as *Aspergillus* spp. and *Pneumocystis carinii* cause fungal pneumonia in horses that are immunocompromised, that are neutropenic, or that have enteritis/colitis, bacterial pneumonia, or neoplasms.[339–345]

Aspergillus is a mold with septate hyphae 2 to 4 μm in diameter. The most prevalent pathogenic species is *A. fumigatus,* but *A. flavus, A. nidulans,* and *A. niger* also may cause disease.[346] These fungi are ubiquitous in the environment, growing on dead leaves, stored grain, compost piles, hay, and decaying vegetation.[336] Inhalation of *Aspergillus* spores is suspected to be common, but disease is rare unless the patient is immunocompromised. Infection is characterized by hyphal invasion of blood vessels, thrombosis, necrosis, and hemorrhagic infarction. Because *Aspergillus* occurs widely as an environmental contaminant, diagnosis may require repeated isolation or histologic demonstration.

Pneumocystis carinii formerly had been considered a protozoan organism because of its morphologic features and its susceptibility to antiprotozoal agents.[347] However, the genes encoding the small subunit ribosomal RNA (16s) and the large subunit of mitochondrial rRNA demonstrate similarities to the genes encoding for the rRNA of several different fungal species.[348] As a result, *P. carinii* recently has been reclassified as a fungus. Electron microscopy has revealed two parasite forms: trophozoite and cystic. The trophozoite is an ameboid form 2 to 5 μm in diameter with filopodia that attach to the surface of the type I epithelial cells. The trophozoite is visible with hematoxylin and eosin stains. The mature cyst is 4 to 6 μm in diameter and contains eight uninucleate intracytic bodies. The cyst stains with Gomori's methenamine silver stain and periodic acid– 329
Schiff stain. In keeping with the new taxonomic classification, some authors recommend replacing the 330
terminology of the different parasite forms by the terms *yeast cell* (trophozoite), *sporangia* (cyst), and *spores* (intracystic bodies).[348]

The infective stage or source of *P. carinii* is unknown, although several studies have reported discovery of *P. carinii* DNA in water and air samples, suggesting that these are environmental reservoirs.[349] In rodent models, *P. carinii* can be transmitted from one animal to another via the airborne route. Researchers also believe that once the organism enters the lower respiratory tract of an immunocompetent host, it remains as a lung saprophyte only to be reactivated during periods of immunosuppression.[347]

7.4.5.2
Epidemiology

Fungal pneumonia in the horse as a primary entity is uncommon. Disease usually results when debilitating conditions that favor the penetration or growth of fungi exist. Contributory factors include (1) exposure to large numbers of mycotic organisms in the environment[350]; (2) the stabling of horses within a moist environment[351]; (3) the prolonged administration of antibiotics that upset the microfloral balance or interfere with vitamin synthesis; (4) the existence of an immunosuppressive state primarily (combined immunodeficiency disorder) or secondarily because of the administration of drugs, the development of an endocrinopathy, or neoplasia.[345,346]

For the pathogenic fungi, prevalence of the disease may be determined geographically. For example, *Blastomyces dermatitidis* is endemic to the Mississippi, Missouri, and Ohio River basins; the Canadian provinces of Quebec, Ontario, and Manitoba; the Great Lakes region; and the Eastern seaboard.[334] Although *Histoplasma capsulatum* is also endemic to the Mississippi, Ohio and St. Lawrence River valleys, it also is found in the southern United States.[338,352] *Coccidiodoes immitis* is endemic to the arid and semiarid regions of North America, including the states of California, Texas, Arizona, New Mexico, Nevada, and Utah.[335,353] In contrast, *Cryptococcus neoformans* is widespread, being found in high concentrations in the soil and in avian manure *(C. neoformans* var. *neoformans)*. In Australia, an epizootiologic relationship of *C. neoformans* var. *gatti* exists with the eucalyptus tree *(Eucalyptus camaldulensis)*. Environmental dispersal of the fungus coincides with flowering of the eucalyptus tree in the spring, resulting in greater exposure and more cases of disease during that time.[354]

For the opportunistic fungus *Pneumocystis carinii,* human clinical infections develop only in immunodepressed subjects, those individuals with low $CD4^+$ counts, with certain viral infections (cytomegalovirus), or in weakened nutritional states.[347,348] To date, all reported cases of equine pneumocystosis have occurred in foals 1.5 to 4 months of age. Predisposing factors include the existence of a combined immunodeficiency disorder,[343] *Rhodococcus equi* or chronic bacterial pneumonia,[344,355] low $CD4^+$ counts,[356] and chronic debilitation or weight loss.[357,358] In two reports of equine pneumocystosis, predisposing factors could not be identified.[359,360] The occurrence of pneumocystosis in young foals may reflect an age-dependent maturation of the immune system. Cell-mediated immune responses (in vitro) of foals less than 2 months of age are reduced relative to those of adult horses, perhaps increasing the susceptibility of the foal to pneumocystosis.[361]

7.4.5.3
Clinical Signs

Horses with primary fungal pneumonia (blastomycosis, histoplasmosis, cryptococcosis, and coccidioidomycosis) may have a chronic cough, anorexia, weight loss, exercise intolerance, and nasal discharge.[362–364] Tachypnea or respiratory distress may or may not be a clinical feature of the fungal pneumonia. Pleural effusion is found more commonly with coccidioidomycosis but also has been reported in cases of cryptococcosis and blastomycosis.[334,335,364]

In addition to causing pneumonia, these fungal organisms may cause disease in other body systems. *Blastomyces dermatitidis* causes superficial abscesses around the anus, vulva, and udder.[365] In a review of 15 cases of equine coccidioidomycosis, 43% of the cases had hepatic lesions, 29% had bone or periosteal

involvement, 22% had lesions in the peritoneum, and 64% had pulmonary parenchymal disorders.[335] Other reports describe *Coccidioides immitis* lesions in the mammary gland,[366] the placenta and fetus,[367,368] and the skin.[369] *Cryptococcus neoformans* has been reported to cause granulomata in the skin, nasal cavity, paranasal sinuses, orbits, intestines, bones, meninges, placenta, and fetus.[354,370–373] *Histoplasma capsulatum* has been associated with abortions, disseminated histoplasmosis of foals, and granulomatous colitis of adult horses.[337,352,374]

Horse developing pneumonia caused by opportunistic fungi (aspergillosis, pneumocystosis) may have evidence of a debilitating or immunosuppressive problem such as colitis, peritonitis, septicemia, endotoxemia, an endocrinopathy, or chronic bacterial pneumonia. Young horses (foals) may be at an increased risk for developing opportunistic infections.

In the majority of cases of pulmonary aspergillosis, pneumonia appears to be a sequelum to mycotic invasion of the intestinal tract, the integrity of which has been compromised by severe acute enterocolitis.[339,340,342,350] Such horses typically also have received broad-spectrum antimicrobials and nonsteroidal antiinflammatory drugs and are neutropenic—factors that may also predispose them to the development of systemic aspergillosis. Nevertheless, pulmonary aspergillosis also has been reported in horses with pleuropneumonia, 330
myositis, renal failure, pituitary adenoma, and myelomonocytic leukemia.[342,345,346] 331

Horses with pulmonary aspergillosis suddenly may become febrile and tachypneic and may exhibit adventitious lung or pleural sounds and have a nasal discharge. Other horses with pulmonary aspergillosis may show only mild respiratory signs or fail to demonstrate any abnormalities of the respiratory tract.[342,374,375]

Pneumocystosis is a rare clinical entity. In the majority of cases, foals have evidence of chronic respiratory disease that has progressed to respiratory distress. Weight loss, dehydration, and inappetence also may be evident.[344,356–358,360]

7.4.5.4 Diagnosis

Tracheobronchial aspirates may reveal degenerated neutrophils, yeast cells, and bacteria. In the case of aspergillosis, the diagnosis may be difficult because one may recover fungal elements from the tracheal washings of normal horses.[24] Definitive diagnosis may require repeated isolation of the *Aspergillus* organisms or histologic demonstration of hyphal elements in the pulmonary parenchyma. Transtracheal aspirates may be of limited usefulness in diagnosing pneumocystosis because the organism rarely is isolated by this method. For horses not in respiratory distress, isolation of the organism may be possible by bronchoalveolar lavage or endobronchial brushings.[344,356–358]

In horses with fungal pneumonia, radiographs may reveal circular masses with or without fluid lines and an accentuated interstitial pattern. Radiography or ultrasonography may detect pleural effusion.

Serologic detection of an antibody response to *Coccidioides immitis, Cryptococcus neoformans,* and *Histoplasma capsulatum* has been useful in diagnosing fungal pneumonia. In cryptococcosis, serologic detection of capsular antigens (serum latex agglutination test) also has proved effective in the diagnosis.[364,370] However, the histoplasmin skin test is of little diagnostic value: in one endemic area, 73% of horses had a postive skin test.[376]

Serologic diagnosis of pulmonary aspergillosis can be difficult because titers are detectable in healthy and diseased horses.[342] Nevertheless, Moore, Reed, Kowalski, et al.[377] reported the existence of two precipitin bands against *Aspergillus* antigens in a horse confirmed to have an *Aspergillus* mediastinal granuloma. Precipitin bands were not evident in the eight control horses sampled. Recently, Guillot, Sarfati, DeBarros, et al.[378] reported the usefulness of an immunoblot analysis for the diagnosis of aspergillosis, detecting reactivity to low-molecular-mass antigens (22 to 26 kd) in the sera of diseased horses that was not evident in clinically healthy horses. The investigators suggested that these antigens were released during mycelial growth in the tissues, a phase that would not develop in clinically healthy horses. However, until this experimental assay is commercially available, one should use serologic diagnosis cautiously in suspected cases of pulmonary aspergillosis. One may confirm the diagnosis with lung biopsy and by the presence of other systemic alterations.

The clinician should investigate cases of immunosuppression by quantitation of immunoglobulin levels, by performing mitogen stimulation tests, by quantitation of $CD4^+$ and $CD8^+$ cells and by ruling out endocrinopathies and neoplasia.

7.4.5.5 Treatment

Treatment against the primary fungal pathogens requires long-term administration (10 to 12 weeks) of antifungal drugs and correction of the inciting cause of the fungal pneumonia. Two basic classes of antifungal drugs are used commonly in equine medicine. The polyene antibiotics—amphotericin B, nystatin, and natamycin—combine with ergosterol in the cytoplasmic membrane of the fungi to increase cell permeability. The second class of drugs, the azoles—miconazole, ketoconazole, itraconazole, and fluconazole—inhibit synthesis of ergosterol and cause an accumulation of aberrant sterols in the membrane. This inhibition affects nutrient utilization and causes leaky cell membranes.[336] Because fungal pneumonia is uncommon, the efficacy of various protocols has not been assessed rigorously. Selection of the antifungal drug to use also should depend on sensitivity patterns of the fungal isolates.

Amphotericin B has been used successfully to treat histoplasmosis[338] and pulmonary aspergillosis.[378] The recommended dose is 0.1 to 0.5 mg/kg administered in a 5% dextrose solution intravenously over 30 minutes, 3 times per week. The possible side effects include anorexia, anemia, arrhythmias, hepatic and renal disyfunction, and hypersensitivity reactions.[372] Neither amphotericin B nor ketaconazole were found to be curative in a series of cases of coccidioidomycosis,[335] although long-term administration of itraconazole (2.6 mg/kg orally twice daily) was eventually effective in treating coccidioidomycosis vertebral osteomyelitis in a foal.[353]

Pneumocystis carinii infections require treatment with antiprotozoal drugs: Ewing, Cowell, Tyler, et al.[358] reported success using trimethoprim sulfamethoxazole (25 mg/kg orally twice daily) in combination with procaine penicillin G in foals with pneumocystosis. Furthermore, Flaminio, Ruch, Cox, et al.[356] supplemented trimethoprim sulfamethoxazole (30 mg/kg orally twice daily) with interferon-α (100 U orally once daily) and *Propionibacterium acnes* (EqStim) in an effort to increase $CD4^+$ and $CD8^+$ counts in a foal with pneumocystosis. The pneumonia eventually resolved and lymphocyte counts returned to normal. 331

7.4.6 MYCOPLASMAL PNEUMONIA

One can isolate several species of mycoplasma from the upper and lower respiratory tracts of healthy horses and from the nasal cavities of healthy foals soon after birth.[379] *Mycoplasma felis* has been isolated from clinical and experimental cases of parapneumonic effusions[327,380,381] and foal pneumonia.[382] *M. felis* and *M. equirhinis* have been isolated, along with bacterial organisms, from the tracheobronchial aspirates of young athletic horses with inflammatory airway disease.[383] Furthermore, a recent Canadian survey documented serologic evidence of *M. felis* or *M. equirhinis* infection in 9% and 10%, respectively, of horses showing clinical signs of acute respiratory disease.[241] The pathogenesis of the inflammatory or infectious airway disease generally is believed to involve adherence of the organism to ciliated epithelium, causing loss of the cilia and subsequent death of the cell. This belief is supported by the finding of degenerative epithelial cells in the tracheobronchial aspirates of horses with mycoplasma infections.[383] Diagnosis of mycoplasmosis depends on isolation of the organism from tracheobronchial aspirates or from pleural fluid and on demonstration of seroconversion. The clinician should initiate treatment with broad-spectrum antibacterials (oxytetracycline) until antimicrobial sensitivity reports are available.

7.4.7 ACUTE RESPIRATORY DISTRESS SYNDROME

7.4.7.1 Causes

Acute respiratory distress syndrome (ARDS) is a syndrome of lung injury characterized by alveolar damage, high permeability pulmonary edema, and respiratory failure. Primary lung injury may result from aspiration (near drowning), improper administration of medications via nasogastric tubes, inhalation of smoke or noxious gases, oxygen toxicity, or pulmonary infection by viral, bacterial, mycoplasmal, or fungal agents. Secondary lung injury may be a sequelum of anaphylaxis, gram-negative sepsis/endotoxemia, trauma and embolism, and hypertransfusion.[384–389] In human medicine, strict criteria have been established to define ARDS: impaired oxygenation (ratio of Pao_2/Fio_2 <200), detection of bilateral pulmonary infiltrates in chest radiographs, and a pulmonary artery wedge pressure less than 18 mm Hg or no clinical evidence of elevated left atrial pressures.[390,391] Similar criteria have not been established in equine medicine.

7.4.7.2 Pathogenesis

Based on the human literature, the thought is that although many different insults (causing capillary permeability) may lead to ARDS, a common final pathway ultimately results in alveolar damage. This pathway may include complement and leukocyte activation with release of oxygen free radicals and inflammatory mediators (IL-1, tumor necrosis factor) and secondary destruction of surfactant.[392] The net result is a deterioration of gas exchange and pulmonary mechanics. Whether horses that survive are more predisposed to the development of interstitial lung disease is uncertain (see the following discussion).

7.4.7.3 Clinical Signs

Horses are tachypneic or in respiratory distress or both. A red-tinged or yellow frothy material, indicative of pulmonary edema, may be evident at the nares. Fever may be a component of the syndrome depending on the

primary cause. In cases of smoke inhalation, clinical signs may not become evident for several days following exposure to noxious gases.

7.4.7.4 Diagnosis

Diagnosis depends on the physical findings and history. One may detect crackles on auscultation and may auscultate fluid within the trachea. Endoscopic examination (if performed without stressing the horse) may reveal the extent of airway edema, inflammation, mucosal necrosis or sloughing, and the presence of soot (smoke inhalation). Radiographs reveal an interstitial pattern, although an alveolar pattern caused by ventral consolidation of the lung fields may follow aspiration pneumonia. Arterial blood gases reveal hypoxemia and hypocapnia, although with carbon monoxide poisoning, oxygen tensions may be normal. In such cases, carboxyhemoglobin concentrations (measured at human hospitals) exceed 10%, indicating carbon monoxide toxicity.[389]

7.4.7.5 Treatment

The clinician should direct treatment at the primary cause with the understanding that prognosis is guarded. Lipoid pneumonia resulting from aspiration of mineral oil is fatal.[385] Cases of near drowning and smoke inhalation have been treated successfully with return to athletic function in some cases.[386,387,393]

One should administer intravenous fluid cautiously. Plasma may be needed if hypoproteinemia develops. Furosemide (1 mg/kg intravenously) helps to mobilize lung extravascular water and repetitive dosing at 2- to 4-hour intervals may be required. (One should monitor electrolytes.) Humidified intranasal oxygen (10 to 15 L/min) or mechanical ventilation through a tracheotomy may be necessary. Although technically difficult to perform, adult horses in respiratory failure have been ventilated mechanically.[394] The clinician may perform tracheal suction to remove cell debris and other materials through the endoscope or through a tracheotomy. Surfactant, although expensive, may improve oxygenation and pulmonary mechanics when administered by 332
intratracheal instillation. One may use bronchodilators to treat bronchospasm. (See the section on recurrent 333
airway obstruction for dosages.) Nonsteroidal antiinflammatory drugs and corticosteroids also are indicated for treating severe permeability edema. One should administer broad-spectrum antimicrobials, including metronidazole, in many of these cases but especially those involving aspiration pneumonia, bacterial and viral pneumonia, and smoke or noxious gas inhalation lung injury.

7.4.8 RECURRENT AIRWAY OBSTRUCTION (HEAVES)

7.4.8.1 Definition

Recurrent airway obstruction is a naturally occurring respiratory disease characterized by periods of reversible airway obstruction caused by neutrophil accumulation, mucus production, and bronchospasm. The condition has been termed *chronic obstructive pulmonary disease, chronic* pulmonary disease, chronic airway reactivity, hyperactive airway disease, broken wind, and *hay sickness*. The consensus at the International Workshop of Equine Chronic Airway Disease was that the term *chronic obstructive pulmonary disease* not be used to describe this condition in horses, because the pathophysiologic and morphologic aspects of the equine disease are different from human chronic obstructive pulmonary disease.[395]

Pulmonary function testing demonstrates a decrease in lung compliance, an increase in lung resistance, an increase in the work of breathing, and the development of arterial hypoxemia, usually in the absence of hypercapnia.[396,397] During airway obstruction, affected horses are hyperresponsive to nonspecific stimuli such as histamine, methacholine, and water.[398]

7.4.8.2 Epidemiology

The condition occurs worldwide, but the highest prevalence in the United States is in northeastern and midwestern horses that are fed hay and stabled. A similar condition, found in horses in the southeastern United States maintained on pasture is termed *summer pasture associated obstructive disease*. These horses improve when stabled.[399] Recurrent airway obstruction effects middle-aged or older horses, the median age of which is 12 years.[400] No breed predilection occurs, but a familial tendency has been found: a horse born to a dam and sire with heaves is at an increased risk for developing heaves.[401]

7.4.8.3 Causes

Much debate still occurs concerning the cause of heaves. Many consider heaves to be a hypersensitivity reaction to organic dusts or molds commonly found in poorly cured hay or straw. Dust in horse stables contains well more than 50 species of molds, large numbers of forage mites, endotoxins, and inorganic components—a variable mixture of agents any one of which might induce pulmonary inflammation in a susceptible horse. The two most frequently implicated molds are *Aspergillus fumigatus* (fungus) and *Micropolyspora faeni* (a thermophilic actinomycete).[402]

7.4.8.4 Pathogenesis

The condition is characterized by periods of reversible small airway obstruction caused by smooth muscle contraction and accumulations of mucus and neutrophils. One hypothesis is that inhalation of the organic molds, dusts, and endotoxin induces an immune response, the nature of which is controversial. A T helper cell type 2 response (TH2), involving IgE-mediated degranulation of mast cells, has been proposed as the inciting cause because of the findings of (1) increased anti– *Micropolyspora faeni* and anti–*Aspergillus fumigatus* IgA and IgE concentrations in the bronchoalveolar lavage (BAL) fluid of asymptomatic and symptomatic heaves-affected horses,[403] (2) increased histamine levels in the BAL fluid of heaves-affected horses 5 hours after natural challenge,[404] (3) increased serum IgE levels against recombinant *Aspergillus* antigens in heaves-affected horses,[405] and (4) increased numbers of BAL cells that are positive for IL-4 and IL-5 messenger RNA in heaves-affected horses.[406]

A T helper cell type 1 immune reaction with secondary neutrophil influx and release of cytokines also has been implicated in the pathogenesis of heaves because (1) correlation of antigen-specific IgE levels with expression of disease is not absolute,[405,407] (2) pulmonary eosinophilia, as occurs in the TH2 disorder of human asthma, is not a feature of heaves,[408] (3) increases in BAL fluid allergen-specific IgGa and IgGb noted by Halliwell, McGorum, Irving, et al. are more compatible with a TH1 rather than with a TH2 response,[403] and (4) quantitative PCR analysis of BAL lymphocytes demonstrates an increase in TH1 (interferon-γ) but not TH2 (IL-4, IL-5) associated cytokines.[409,410]

In horses with heaves, IL-8 concentrations in the bronchoalveolar fluid are increased relative to levels found in healthy horses.[410,411] This cytokine may be derived from macrophages, neutrophils, or airway epithelial cells and is one of the primary chemoattractants for neutrophil migration into the airways. Interestingly, in murine models of obstructive airway disease, airway epithelial cell production of IL-8 is upregulated by interferon-γ and IL-17.[412] Because the mRNA levels of IL-17, a T cell–derived cytokine, also increased in airway lymphocytes isolated from heaves-affected horses (Ainsworth, unpublished data), a link between the airway TH1 responses and epithelial-derived chemokines may exist.

Neutrophil- and macrophage-derived products such as reactive oxygen species and proteases also may 333
contribute to the inflammatory process of heaves. Art, Kirschvink, Smith, et al.[413] suggested that an oxidative 334
stress caused by the release of reactive oxygen species from granulocytes and macrophages develops in the airways of heaves-affected horses. Their conclusion is based on the finding that oxidized glutathione levels and glutathione redox ratios (the ratios of oxidized glutathione to total glutathione levels) are elevated in the pulmonary epithelial lining fluid of heaves-affected horses relative to controls. They further suggested that the oxidant stress does not incite but rather exacerbates the existing inflammation. Interestingly, oxidative stress[414] has been found to activate NFκB, a transcription factor that regulates the expression of many proinflammatory cytokines and adhesion molecules including tumor necrosis factor α, IL-1β, IL-8, and intercellular adhesion molecule 1.[415] Recently, Bureau, Bonizzi, Kirschvink, et al.[416] demonstrated that levels of NFκB in the bronchial brushing cells of heaves-affected horses were increased many times, the magnitude of which correlated with the severity of the clinical disease. Furthermore, the airway epithelial cell expression of intercellular adhesion molecule 1, a protein required for migration of neutrophils from the pulmonary vasculature into the lung parenchyma, paralleled the expression of NFκB, suggesting that this protein, along with IL-8, enhances the airway neutrophilia.

Proteases released from neutrophils (and macrophages) in the airways of heaves-affected horses may contribute further to inflammatory cell influx and possible tissue damage. Researchers have found that the tracheal epithelial lining fluid of horses with heaves has increased concentrations of matrix metalloproteinases that exhibit collagenolytic, gelatinolytic, and elastinolytic activities.[417–419] The importance of these proteases, as well as other inflammatory mediators and arachidonic acid metabolites, to the initiation and development of bronchospasm, mucus secretion, and neutrophil influx needs to be determined.

7.4.8.5 Clinical Signs

Horses with heaves have a chronic spontaneous cough, a mucopurulent nasal discharge, an accentuated expiratory effort, and adventitious lung sounds. Hypertrophy of the external oblique and rectus abdominis muscles caused by continued recruitment is evident (heave line). The respiratory rate may be normal or increased (tachypnea). Exercise intolerance, weight loss, and cachexia also may be evident in severe cases. Horses are usually afebrile.

7.4.8.6 Diagnosis

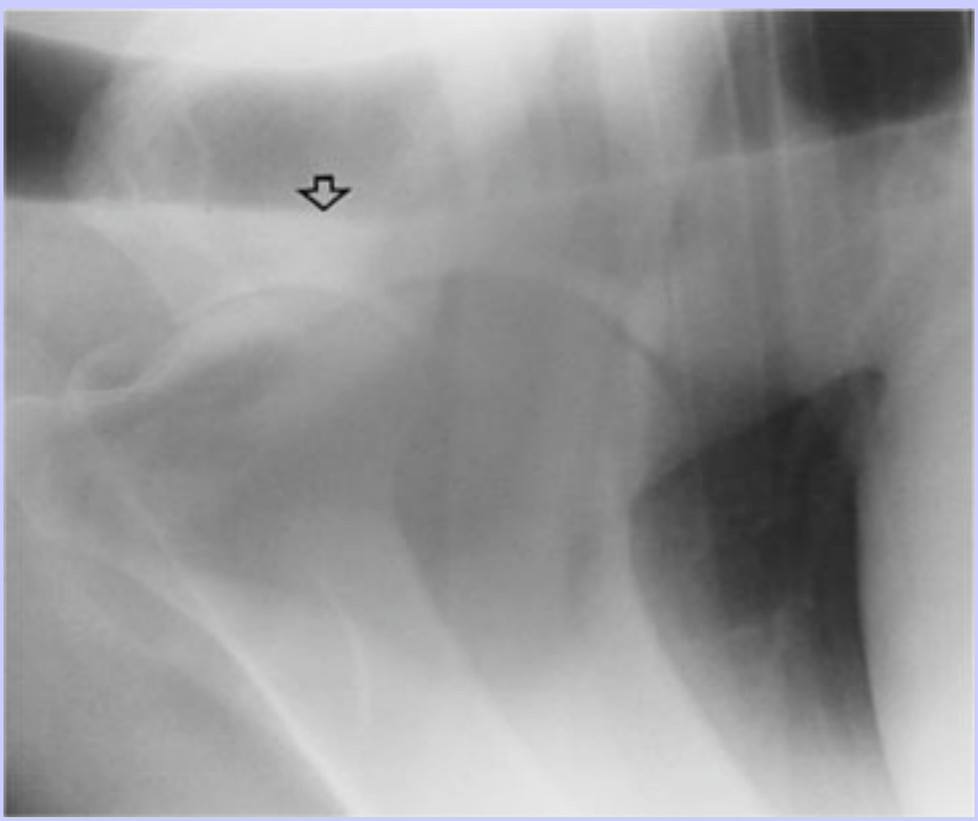
Diagnosis is based on the clinical signs and history of a seasonal disorder associated with husbandry alterations such as being fed hay, stabled, transported in a trailer, or maintained in a dusty lot. Auscultation may reveal inspiratory or expiratory wheezes, crackles, or tracheal rattles. Percussion may be normal or an expanded lung field may be detectable.

Endoscopic examination reveals excessive mucopurulent exudate within the trachea. A bronchoalveolar lavage supports a *nonseptic* inflammatory reaction with increases in mucus and the percentage of intact neutrophils. Albumin and immunoglobulin levels within the bronchoalveolar lavage may not increase.[420] Gram-positive organisms may be retrieved by tracheobronchial aspirates if a concurrent septic inflammation exists. Pollen, fungal hyphae, and Curschmann's spirals (inspissated mucus plugs) also may be visible.

Thoracic radiography may demonstrate an increase in the interstitial and bronchial pattern throughout the lung fields. However, these changes may be difficult to interpret relative to the normal aging changes that occur. One also may detect exudate within the trachea by thoracic radiography (Figure 7-19).

Some have advocated intradermal skin testing for diagnosing heaves and for detecting sensitizing allergens. Its usefulness is questionable. Theoretically, heaves-affected horses should react if sensitized to a given allergen, but (1) clinically normal horses have positive skin test reactions to the allergens and (2) heaves-affected horses lack positive reactions. Thus intradermal skin testing is not indicated for diagnosing heaves.[421–423] Furthermore, a poor correlation exists between skin test results and serum allergen testing, leading some clinicians to conclude that these assays should not be used as screening tests for allergen hypersensitivities in the horse.[423]

Figure 7-19 Tracheal fluid or exudates *(arrow)* is visible ventrally in the trachea at the level of the thoracic inlet. (Courtesy D.S. Biller, Manhatten, Kansas, 1991.)



A CBC and serum chemistry panel is of limited usefulness in diagnosing heaves because no abnormalities are detectable in the leukogram or in serum biochemistries.[400]

7.4.8.7 Pathologic Signs

Postmortem examination reveals a diffuse bronchiolitis with goblet cell metaplasia, airway smooth muscle hypertrophy, excess mucus, and inflammatory cells in the small airways. Eosinophilic infiltration around the bronchioles is a variable finding, present in approximately one third of the horses. Varying degrees of alveolar overinflation and atelectases also are found, as well as evidence of fibrosis of the alveolar septa.[424] The larger airways—the bronchi and trachea—also may show variable changes, including epithelial hyperplasia with loss of ciliated cells, goblet cell hyperplasia, and inflammatory cell infiltration.[425]

7.4.8.8 Treatment

Elimination of the source of the mold or dust is the most beneficial step in the treatment regimen but also the most difficult management change to implement.[400] Horses should be fed a pelleted alfalfa or a complete pelleted feed with the transition from a hay diet to one of a complete pelleted feed made gradually over 7 to 10 days. Unless pasture exacerbates the condition, the owner should keep horses outside, blanket them in the winter, and allow access to a three-walled shelter affording protection from the wind and rain. If the horse is stabled, the stall bedding should be shredded paper, shavings, peat moss, or clay to eliminate dusts and molds. The surrounding stalls should be bedded similarly. Although such stabling changes improve lung function somewhat, airway hyperreactivity still remains.[426,427]

Medical management also has been indicated in clinical cases because stabling alone takes several weeks to quiet the pulmonary inflammation. Corticosteroids are efficacious in reducing the inflammatory reaction in the lungs, whereas nonsteroidal antiinflammatory drugs provide no benefit. The clinician initially may give prednisolone (not prednisone) at 2.2 mg/kg orally once daily in the morning for 7 to 10 days, 1.1 mg/kg once daily for 7 to 10 days, 0.50 mg/kg once daily for 7 to 10 days, and 0.50 mg/lb every other day for 7 to 10 days. Alternatively, one may give a course of dexamethasone parenterally. For the 500 kg horse, the course is 40 mg intramuscularly once daily every other day for three treatments, followed by 35 mg intramuscularly once daily every other day for three treatments, 30 mg intramuscularly once daily every other day for three treatments, etc., until the horse is weaned off of the dexamethasone. Corticosteroid use may be contraindicated in horses predisposed to laminitis or exhibiting endocrinopathies.

Inhaled steroids have been used to treat the pulmonary inflammation of heaves but may not provide a therapeutic benefit for 24 to 72 hours. Thus for horses in respiratory distress, inhaled steroids should not be the main route of glucocorticoid administration. Metered dose inhalers attached to a spacer on the Aeromask (Trudell Medical, London, Ontario, Canada) administer the drug when the horse initiates inspiration. Frequent administration of steroids to effect improvement in lung function may make this medical treatment less desirable. Some suggested corticosteroid dosages (using the Aeromask) are beclomethasone (3750 μg twice daily) or fluticasone (2 μg twice daily).

Bronchodilators also are recommended for treating recurrent airway obstruction. Three types of compounds are used to relax airway smooth muscle: the β-adrenergics, the methylxanthines, and the anticholinergics. The β_2-adrenergic compounds include clenbuterol, albuterol, salmeterol, and fenoterol. Experimental investigations with clenbuterol suggest that when given at a dose of 0.8 μg/kg once daily by mouth, the drug

may be efficacious in alleviating some of the signs of heaves. In addition to a direct smooth muscle effect, clenbuterol also may stabilize mast cells, increase mucociliary clearance, and improve airway secretions.[428] Albuterol is absorbed poorly from the gastrointestinal tract, so inhalation is the recommended method of administration. Some suggested dosages of β_2-agonists that can be administered by metered dose inhalers through the Aeromask are these: albuterol, 720 μg 3 to 4 times daily; fenoterol, 1 to 2 μg 3 to 4 times daily; and salmeterol, 210 μg once or twice daily. Administration of the β_2-agonist before corticosteroid dosing enhances the deposition of the latter in the smaller airways.[429] Long-term use of β_2-agonists has been associated with a downregulation of the β-receptors in human beings, but whether this occurs in horses is unknown.

The methylxanthines include aminophylline (theophylline), which dilates smooth muscle by increasing cyclic adenosine monophosphate levels intracellularly. Cyclic adenosine monophosphate also inhibits degranulation of mast cells and subsequent mediator release. One may give aminophylline at 4 to 6 mg/kg orally 3 times daily. However, in a recent study, aminophylline 18 mg/kg intravenously provided clinical improvement in only 50% of the cases.[430]

The third class of compounds used to effect smooth muscle dilation includes the anticholinergics, of which atropine and glycopyrrolate are representatives. Atropine provides clinical improvement when administered intravenously at 0.02 mg/kg, but the duration of effect is short-lived (2 hours) and atropine may be associated with the development of ileus, abdominal pain, tachycardia, mydriasis, and thickening of airway secretions.[430] 335
Atropine generally is used for emergency relief of airway obstruction. Glycopyrrolate has been reported to be 336
efficacious at a dose of 0.007 mg/kg, but it also may cause colic. One also can administer ipratropium bromide by inhalation at a dose of 180 to 360 mg 3 times daily with a low risk of inducing systemic side effects.[395]

Disodium cromoglycate is considered efficacious by some, acting to stabilize mast cell degranulation and inhibit the vagal efferent component of histamine response. A suggested dose from the study of McPherson and Thomson[402] was 80 mg once daily for 4 days by nebulization. Mucolytics (acetylcysteine, dembrexine) and mucokinetics (iodides, bromhexine) may provide some relief.[431] Antimicrobials are indicated if microorganisms are isolated on the tracheobronchial aspirate.

7.4.8.9 Prevention

Once the clinician has diagnosed the condition, the horse always will be susceptible to recurrences of the disease. Husbandry changes should be implemented to decrease environmental dust and organic mold exposure. During periods of hot, humid, or dusty conditions, prophylactic administration of a steroid and bronchodilator via the metered dose inhaler may be indicated. Routine immunizations against the viral respiratory pathogens and good management practices are logical suggestions.

7.4.9 INFLAMMATORY AIRWAY DISEASE

7.4.9.1 Definition

Inflammatory airway disease (IAD) is characterized by the presence of excessive amounts of mucoid or mucopurulent exudate in the nasopharynx, trachea, and bronchial bifurcation. The condition is encountered predominantly in the young performance horse.[47,89] Auscultatable pulmonary abnormalities rarely are

identified. Some horses with IAD may exhibit a cough and reduced athletic performance. The relationship between IAD in young horses and recurrent airway obstruction in mature horses is unknown: currently, the former condition is believed not necessarily to progress to the latter.[395]

7.4.9.2 Epidemiology

Depending on the study, a prevalence of 20% to 65% among racehorses in training has been noted.[89,432] The variation in prevalence may reflect the method of diagnosis: the amount of tracheal exudates detected endoscopically increases as a function of exercise intensity.[89] Thus one may miss the diagnosis of IAD if one performs endoscopic examination in the resting horse.[433]

7.4.9.3 Causes

The definitive cause of the lower airway inflammation is currently unknown and has been hypothesized to reflect the response of the lung to the presence of (1) low-grade persistent bacterial or viral infections, (2) autologous blood from exercise-induced pulmonary hemorrhage, and (3) inhaled dusts, molds, particulate matter or environmental pollutants such as H_2S, NH_3, ozone, SO_2, NO_2 and CO.

Studies in the United Kingdom and Australia suggest that bacterial agents are involved in the pathogenesis of IAD.[89,434–436] Using an inflammatory score based on the amount of mucus, total nucleated cell count, and neutrophil percentages in endoscopically obtained tracheobronchial aspirates, investigators found that as the inflammatory score increased, the percentage of positive bacterial cultures also increased.[437] The most commonly isolated organisms were *Streptococcus zooepidemicus, Streptococcus pneumoniae, Actinobacillus equuli,* and *Pasteurella* spp. Mycoplasma spp. also were isolated from some horses with IAD.[383] That the prevalence of IAD decreased with increasing age of the horse was attributed to the development of an effective immune response. In studies in the United Kingdom and in Australia (where equine influenza is not endemic), no association between the onset of IAD and seroconversion to EHV1, ERV1, ERV2, or equine influenza existed,[434,436,438] suggesting that IAD is not associated with a viral infection.

A viral cause has been proposed for IAD based on the cytologic improvements in BAL fluid constituents in horses treated with oral interferon-α. In their study of 32 Standardbred horses with a history of poor performance referable to the respiratory tract, Moore, Krakowka, Robertson, et al.[439,440] and Moore, Krakowka, McVey, et al.[441] found that relative to control horses, the BAL fluid total nucleated cell count and the percentages of BAL fluid neutrophils, lymphocytes, and monocytes increased significantly in horses with IAD. They considered the lymphocytosis and monocytosis to be consistent with a low-grade viral infection. A 5-day course of oral interferon-α (50 U per day) lowered total nucleated cell counts and converted the cell distribution to a noninflammatory profile for at least 15 days. The investigators did not describe whether the amelioration of pulmonary inflammation was associated with an improvement in athletic performance. They also did not evaluate horses endoscopically beyond 2 weeks to determine if cessation of interferon-α therapy was associated with a return of IAD.

Autologous blood, derived from pulmonary capillaries that rupture during intense exercise, also has been suggested to cause of IAD. In an experimental study, Tyler, Pascoe, Aguilera-Tejero, et al. found that instillation of blood caused a neutrophilic pulmonary inflammatory reaction in the lungs, leading them to conclude that pulmonary hemorrhage may contribute to IAD.[442]

Evidence that inhaled environmental allergens from hay or straw contribute to IAD is supported by the observations that episodes of IAD are shorter in horses bedded on shredded paper[434] and that stabling is associated with an increase in the proportion of BAL fluid neutrophils and a decrease in the percentage of lymphocytes.[91]

Hare and Viel[443] also have suggested that a type I (IgE-mediated) hypersensitivity reaction to inhaled environment allergens could be the cause of IAD. They studied young Standardbred racehorses with a history of poor performance and found evidence of peripheral blood and BAL fluid eosinophilia (12% eosinophils). Normally the percentage of eosinophils in BAL fluid is less than 2%. Because they found no evidence of pulmonary or intestinal parasitism in this group of affected horses, the investigators attributed the eosinophilic IAD to an allergic reaction.

Environmental pollutants also have been suggested as a cause of IAD. This hypothesis arises from the observation that many racetracks and training facilities are located in metropolitan areas that have significant accumulations of smog. No data exist verifying this as a cause of IAD.

7.4.9.4 Clinical Signs

Inflammatory airway disease is frequently subclinical but in some cases may be associated with poor athletic performance or a cough. With the exception of the cases described in England, pyrexia is generally not a feature of the disorder. Horses also may have evidence of EIPH.

7.4.9.5 Diagnosis

Definitive diagnosis requires endoscopic examination of the respiratory tract with the finding of exudate in the nasopharynx and in the trachea. One also may see lymphoid hyperplasia depending on the age of the horse. Other causes of poor performance—musculoskeletal and cardiovascular—must be ruled out to attribute reduced athleticism to IAD. This may require that the horse perform a standardized treadmill exercise test, enabling assessment of the upper respiratory tract (videoendoscopy), the cardiovascular system (electrocardiogram), and the musculoskeletal system (lameness exam, creatine kinase and aspartate transaminase measurement). One also should obtain a CBC and chemistry panel. With the exception of cases of IAD associated with pulmonary eosinophilia, CBC and chemistry profiles are usually within normal limits.

Further diagnostic evaluation of the respiratory system in horses with IAD should include a culture of a tracheobronchial aspirate to rule out a low-grade bacterial infection and a bronchoalveolar lavage to determine whether the cytologic profile is most representative of a bacterial, viral, or allergic cause.

Although instillation of autologous blood does decrease dynamic compliance and increase respiratory resistance[444] in the majority of investigations of IAD, pulmonary function tests have been unremarkable.[47,443] Measures of airway hyperreactivity, performed by determining dose-dependent alterations in respiratory tract resistance or dynamic lung compliance following nebulizing of methacholine or histamine, have demonstrated that some horses with IAD have hyperresponsive airways.[47,443,445]

7.4.9.6
Treatment

Because the cause of IAP remains uncertain, most treatment recommendations aim at environmental alterations to decrease exposure to dust, molds, and allergens. Horses should have pasture turnout whenever possible. Horses with bacterial infections should receive a 7- to 10-day course of an antibiotic, the selection of which is based on culture and sensitivity results from the tracheobronchial aspirate. Horses with pulmonary lymphocytosis and monocytosis may benefit from a 5-day course of orally administered interferon-α (50 U once daily). One also should implement efforts to decrease the severity or frequency of EIPH by having horses train and race with furosemide. In the absence of an infectious cause, horses also may benefit from a course of corticosteroids: prednisolone at 1 mg/lb orally once daily for 7 to 10 days, followed by 0.5 mg/lb orally once daily for 7 to 10 days, and then 0.5 mg/lb orally once every other day for 7 to 10 days.

7.4.10
LUNGWORMS

7.4.10.1
Causes

Lungworm infections in the equine species are caused by *Dictyocaulus arnfieldi*. Infections in the donkey and mule are asymptomatic but provide a source of viable eggs for clinically apparent infections in the horse and pony.

7.4.10.2
Epidemiology

Lungworm infections have been diagnosed by recovery of larvae in live animals by bronchoscopic examination[446] or at postmortem evaluation. Using this approach, the prevalence of lung worm infection is approximately 68% to 80% in donkeys, 29% in mules, and 2% to 11% in horses.[447,448]

7.4.10.3
Pathogenesis

Donkeys are asymptomatic reservoirs of the parasite, but instances of lungworm infections have occurred in horses in which no contact with donkeys could be established, suggesting horse-to-horse transmission may be possible.[448] Experimental studies provide evidence that under field conditions, *Pilobolus* fungi may facilitate 337
the spread of lungworm infections in a manner similar to that which occurs in cattle lungworm infections.[449] 338
The infective larvae ascend the coprophilous fungus as it grows on the manure and invade the sporangia. When the sporangia rupture, the infective larvae disperse with the fungal spores. After the infective larvae (0.4 mm) are ingested, they migrate through the gut wall and are carried to the lungs via the lymphatics. In hosts in which infections are patent, the larvae mature to egg-laying adults in the peripheral bronchioles. The prepatent period is approximately 2 to 3 months. Eggs are transported out of the lungs by the mucociliary apparatus, swallowed, and excreted in the feces where they become infective by 4 days.[450] First-stage larvae have survived for at least 49 days but do not survive over the winter.[451] In horses and ponies, larval development in the lungs is arrested (fifth stage), but airway inflammation still occurs.

7.4.10.4 Clinical Signs

Horses exhibit chronic coughing and an increased expiratory effort. Auscultation reveals crackles and wheezes, especially over the dorsal and caudal parts of the lung fields.[452] Signs are often indistinguishable from those associated with heaves. Donkeys do not typically exhibit clinical signs of infection.

7.4.10.5 Diagnosis

Endoscopic examination may reveal a mild lymphoid follicular hyperplasia and copious amounts of exudate in the trachea and bronchioles. Tracheobronchial aspirates or bronchoalveolar lavage may contain a predominance of eosinophils. A peripheral eosinophilia is a variable finding in these horses. Definitive diagnosis is made by identification of *D. arnfieldi* larvae in the sediment of centrifuged mucus, although this may be difficult.[451] One should examine stained and unstained cytologic preparations. In donkeys and in horses with patent infections, bronchoscopic identification of the lungworm, 16 cm in length, confirms the diagnosis. The Baermann technique is useful for diagnosing lungworms when the infections are patent.

Diagnosis most often depends on the clinical signs, the history of exposure to donkeys, and the response to anthelmintic therapy.

7.4.10.6 Treatment

Ivermectin (200 μg/kg) is effective against *D. arnfieldi* in controlled studies and field evaluations and did not cause any detrimental side effects.[453] Moxidectin (0.4 mg/kg) was found to be 99.9% effective in treating lungworm infections in donkeys.[454]

7.4.10.7 Prevention

Horses should not be pastured with donkeys or mules unless they are confirmed to be free of lungworms.

7.4.11 EXERCISE-INDUCED PULMONARY HEMORRHAGE

7.4.11.1 Causes

Strenuous exercise is associated with exudation of red blood cells from the pulmonary vasculature into the alveoli and airways of the caudal dorsal lung segments.

7.4.11.2 Epidemiology

EIPH has been detected in most breeds of horses undergoing strenuous athletic events. The prevalence of EIPH is estimated to be between 44% and 75% in the Thoroughbred, 26% in the Standardbred, 62% in the racing Quarter Horse, 50% in racing Appaloosas, 68% in steeplechasers, 67% in timber racing horses, 40% in Three-Day Event horses, 10% in pony club event horses, and 11% in polo ponies.[455–459] Indeed, EIPH probably occurs in any breed of horse that is exercised strenuously. The prevalence of EIPH increases with the

age of the horse. No clear correlation exists between EIPH and the location of stables, the condition of the track, or the track type.[460] No geographic variation exists in the prevalence of EIPH.

7.4.11.3 Pathogenesis

The mechanisms responsible for the development of EIPH are not known completely, although potential causes include (1) ventilation inhomogeneities caused by small airway disease, (2) mechanical constraints of abdominal viscera placed on the dorsocaudal lung field, and (3) stress failure of the pulmonary capillaries.

Robinson and Derksen[461] proposed that poor collateral ventilation in the horse coupled with small airway disease (and thus altered time constants for alveolar filling) caused underventilation of certain lung units. Extreme fluctuations in the alveolar pressure of these underventilated regions during exercise produced parenchymal tearing or alveolar capillary rupture. Small airway disease (IAD) has been detected in a large percentage of horses with EIPH[462]; however, its absence in the lungs of young racehorses that still exhibit evidence of EIPH suggests that small airway disease, at least, is not an inciting cause of EIPH.[463] The role of small airway disease in propagating the cycle of EIPH cannot be dismissed.

Clarke[464] speculated that visceral constraint of the diaphragm caused greater mechanical forces or stresses to develop in the dorsal thorax. Thus in the caudodorsal lung, these mechanical forces would be borne over a narrow area, leading to parenchymal tearing or rupture of capillaries during inspiration. However, evidence of widespread hemorrhage in the dorsal portions of the lung suggests that the distribution of extremely negative intrapleural pressures is more complex and not simply restricted to the region in close proximity to the caudal dorsal lung. An alternative mechanical theory has proposed that forelimb locomotory impact forces are 338
transmitted through the chest wall, setting up waves converging caudodorsally in the lung parenchyma.[465] 339
Experimental evidence supporting the mechanical theories is currently not available.

Pulmonary hypertension and secondary stress failure of the capillaries also has been suggested as the cause EIPH. Stress failure is thought to occur following development of high transmural pressures, the pressure difference between the pulmonary capillary bed and the adjacent alveoli. Pulmonary capillary pressures (which may exceed 70 mm Hg in strenuously exercised horses) disrupt capillary endothelial and alveolar epithelial tight junctions leading to hemorrhage within the interstitium and alveoli. The pulmonary hypertension is a consequence of the high cardiac output, the lack of sufficient pulmonary vascular vasodilation and the increased blood viscosity during exercise. Evidence supportive of the stress failure theory is provided by electronmicrographs prepared from lung segments taken from strenuously exercised horses. These demonstrate a breakdown of the endothelial and epithelial tight junctions and exudation of red blood cells into the alveoli.[466] Although some investigators have found no correlation between pulmonary capillary pressures in exercising horses and the development of EIPH ascertained endoscopically,[467] others have found a correlation between mean pulmonary artery pressures in exercising horses and the number of erythrocytes in postexercise bronchoalveolar lavage fluid samples.[468]

A combination of these three mechanisms likely may contribute to the development of EIPH.

7.4.11.4 Clinical Signs

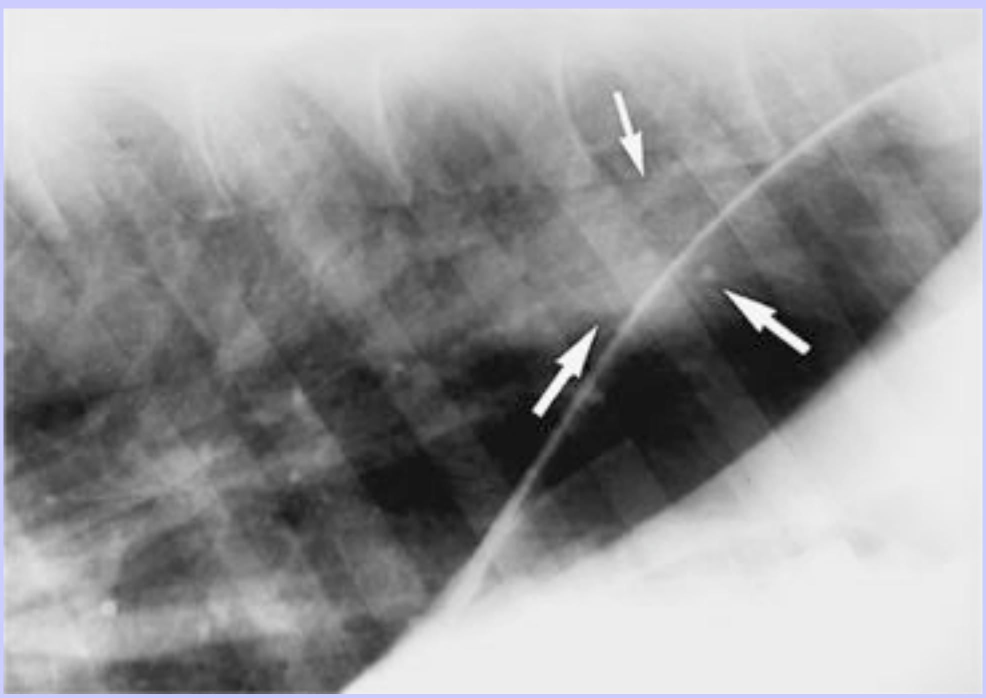
Evidence of frank blood occurs in less than 10% of the horses with EIPH. The effect of EIPH on racing performance varies. A clear association between finishing position in a race and the prevalence of EIPH in

Thoroughbreds or Standardbreds has not been demonstrated. Often horses continue to perform at levels judged to be adequate. In other cases, horses may slow or stop, and some may exhibit difficult or labored breathing, coughing, or excessive swallowing. The affect of EIPH on athletic performance may be better understood when methods to quantitate the extent of bleeding have been developed.

7.4.11.5 Diagnosis

Endoscopic examination of the upper respiratory tract and detection of frank blood within the trachea is the usual method of diagnosis. Optimal time for endoscopic examination is within 90 minutes of a race or workout. However, EIPH is not a consistent finding; it may not be apparent in a given horse examined on different occasions after the same level of exercise. Transtracheal aspirates or bronchoalveolar lavage reveals hemosiderophages, intact and degenerating neutrophils, some with intracellular bacteria, and erythrocytes. Radiographs may demonstrate increases in interstitial patterns, a radiopaque region in the caudal lung lobe (rare), and possible dorsal displacement of the major pulmonary vessels[469] (Figure 7-20).

Figure 7-20 Focal area of increased interstitial pulmonary opacity *(arrows)* in the dorsal caudal lung field represents exercise-induced pulmonary hemorrhage. (Courtesy D.S. Biller, Manhatten, Kansas, 1991.)



7.4.11.6 Treatment

Rest has been recommended, but pulmonary hemorrhage likely will recur once the horse resumes training. The finding of concomitant small airway disease (IAD) in some horses suggests that one should attempt to

minimize environmental dusts and molds. Corticosteroids and bronchodilators, inhaled or administered parenterally, have not been shown to reduce EIPH but may lessen the severity of small airway disease. Cromoglycate, which is believed to stabilize mast cell membranes, has not been efficacious in the treatment of EIPH.[470]

Antimicrobials may be indicated in cases of severe hemorrhage because blood provides an excellent medium for bacterial growth to occur.

Drugs that reduce pulmonary capillary pressure have gained the most widespread use in the treatment and prevention of EIPH. Furosemide, 250 to 300 mg, is given 4 hours before a race or strenuous workout. Although furosemide admnistration has failed to prevent the development of EIPH in horses that were previously EIPH-negative,[471,472] some evidence indicates that it may reduce the severity of EIPH (red blood cell counts in bronchoalveolar lavage fluid). Nitric oxide, a potent vasodilator, also has been administered to horses in the form of nitroglycerin. However, nitric oxide reduces neither pulmonary artery pressures of strenuously exercising horses nor the severity of EIPH.[473,474] 339

340

7.4.11.7 Prevention

The efficacy of treatment regimens in the prevention of EIPH under race conditions has been difficult to determine even when speed handicapping methods are used. Variables such as the administration of drugs unknown to the investigators or the inability to diagnose or reproduce EIPH within a given horse on consecutive days makes interpretation of these studies difficult. And yet controlled studies conducted on a treadmill probably do not accurately simulate race conditions, so that one also may draw false conclusions.

7.4.12 INTERSTITIAL LUNG DISEASE

7.4.12.1 Definition

Although traditionally considered to be a chronic disorder, interstitial pneumonia encompasses acute and chronic inflammatory responses that predominantly involve the alveolar walls and interstitial tissues of the lung.[475] Interstitial lung disease includes a heterogeneous group of disorders characterized by damage to the alveolar walls and loss of functional alveolar capillary units. This is a morphologic characterization of a lung disease. These authors believe it possible that cases of ARDS may progress eventually to interstitial lung disease. However, longitudinal studies supporting this hypothesis have not been conducted.

7.4.12.2 Epidemiology

Buergelt[476] has suggested that two types of equine interstitial disorders exist: one occurring in foals 6 days to 6 months of age and one developing in adult horses greater than 2 year of age. This discussion focuses on interstitial lung disorders in the adult horse.

7.4.12.3 Causes

Most of the recognized spontaneously occurring interstitial lung disorders in animals have been attributed to toxic or infectious (viral or parasitic agents) agents or to allergens.[475] Toxic lung injury in the horse has been

documented following consumption of Crofton weed, pyrrolizidine alkaloids, and *Perilla* ketones.[475–478] Interstitial pneumonia is a feature of viral infections (influenza, EHV1, EHV4, EVA), silicosis, and possibly oxygen therapy.[479,480] Other cases of interstitial pneumonia may not have a well-defined cause.[481–484]

7.4.12.4 Pathophysiology

An inciting agent initiates damage to pulmonary epithelial or endothelial cells, causing coagulative necrosis of the alveoli. Pulmonary congestion, interstitial edema, erythrocyte extravasation, and alveolar flooding characterize the acute (exudative) phase of the disease. Fibrin, protein-rich fluid, cellular debris, and inflammatory cells (neutrophils and macrophages) form hyaline membranes. During the acute phase (days 1 to 5), the horse may exhibit respiratory distress. The exudative phase is followed by a proliferative stage in which the type II pneumocytes, the pulmonary stem cells, replace damaged type I pneumocytes. Interlobar septa widen because of the proliferation of fibroblasts and inflammatory cell infiltration by neutrophils and macrophages.[475]

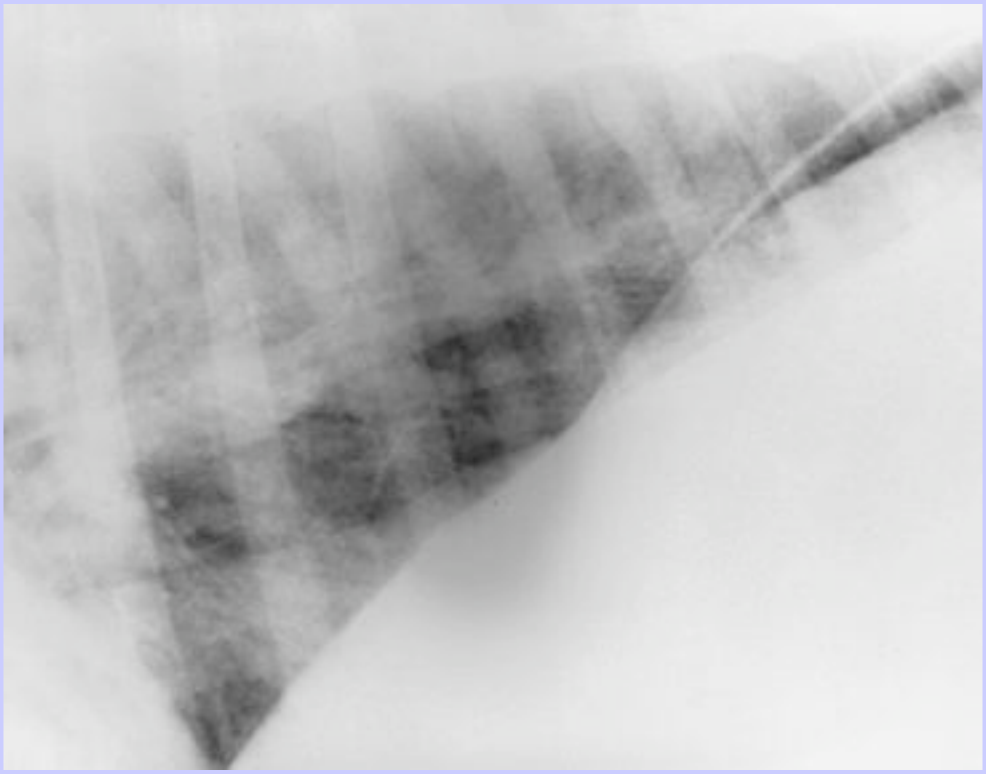
7.4.12.5 Clinical Signs

Clinical signs vary depending on the stage of the pneumonia and the causative agent. In the acute phase, horses may have respiratory distress: they are tachypneic, may be hypoxemic, and may or may not be febrile.[478,479] Horses also may have signs similar to those exhibited by heaves-affected horses with an increased respiratory rate and a significant expiratory effort, cough, and nasal discharge.[481–483] In chronic disorders, horses may exhibit exercise intolerance[482] or have a history of weight loss and anorexia. Interstitial lung disease also may be present in the absence of clinical signs.[482]

7.4.12.6 Diagnosis

The diagnosis is based on clinical signs, history, radiographic examination, isolation of a causative agent, and lung biopsy. Arterial hypoxemia may be evident on blood gas analysis. CBC and serum chemistry panels may be normal or may demonstrate leukocytosis and hyperfibrinogenemia.[485,486] Radiographs demonstrate (1) pulmonary infiltrates with discrete and diffuse nodules, suggesting neoplasia or mycotic pneumonia, or (2) an 340
increase in the interstitial pattern of the lung (Figure 7-21). Serum titer levels may indicate a high titer to 341
equine influenza virus.[479] Lung biopsy confirms the diagnosis of interstitial pneumonia. Silicosis, also a rare finding in the horse, is diagnosed by using x-ray diffraction techniques on lung tissue specimens.[480]

Figure 7-21 Overall increase in interstitial pulmonary opacity represents interstitial lung disease. (Courtesy D.S. Biller, Manhatten, Kansas, 1991.)



7.4.12.7 Pathologic Signs

The lung changes are a function of the stage and the causative agent. Postmortem examination may reveal diffuse pulmonary fibrosis and hypercellularity of alveolar septa and scarring of the interlobular septa and parts of the pleura. Severe chronic bronchitis and bronchiolitis also may be evident if concurrent airway disease exists, but this is typically not a feature of interstitial pneumonia.[482] Multifocal granulomata may be detectable.[480,483]

7.4.12.8 Treatment

The prognosis is poor for resolving the interstitial lung disorder. In one study of six adult horses presented to a veterinary clinic for chronic respiratory disease, one horse improved.[482] In another study, long-term glucocorticoid therapy improved the pulmonary disorder sufficiently to allow the horse to return to athletic performance.[485]

7.4.13 TUMORS OF THE RESPIRATORY SYSTEM

7.4.13.1 Causes

Based on postmortem surveys, the most frequently encountered equine tumors are sarcoids, squamous cell carcinomata, fibromata, melanomas, papillomata, fibrosarcomata, and lymphomata.[486–488] Neoplastic involvement of the pulmonary parenchyma or thoracic structures per se remains rare in horses, occurring at a prevalence rate of 0.15 to 0.62.[326,488]

Primary equine lung tumors include granular cell tumors (myoblastomata),[489–492] bronchial myxomata,[493] pulmonary carcinomata[486,494] pulmonary adenocarcinomata,[495,496] and pulmonary chondrosarcomata.[497,498] Primary thoracic tumors include pleural mesotheliomata,[432,499] thymomata,[326] and lymphomata.[326,500]

The incidence of primary lung tumors is much less than that of metastatic pulmonary tumors. The most common primary lung neoplasm is the granular cell tumor, with a prevalence rate of 0.15%. Most granular cell tumors involve the right lung, may be multiple or single masses, may be associated with airway obstruction, and are visible with endoscopic examination.[491,492] Based on immunohistochemical staining, granular cell tumors are thought to be composed primarily of myelinating Schwann cells with lesser numbers of scattered nonmyelinating Schwann cells.[501,502]

Metastatic lung tumors include adenocarcinoma (primary sites of origin are in the kidney, uterus, thyroid, ovary, and mammary gland),[323,324] hemangiosarcoma (primary sites of origin are in the skeletal musculature or are undetermined),[326,503–510] and lymphoma.[326,500]

Hemangiosarcoma remains a rare tumor, occurring in 2 in 1322 horses in a study by Sundbery, Burnstein, Page, et al.[487] and in 1 in 4739 cases in a survey reported by Hargis and McElwain.[506] Many of the reported cases of hemangiosarcoma involve horses less than 7 years of age.[503,507–510] Typically, horses exhibit pallor of the mucous membranes because of anemia, have evidence of pleural effusion (hemorrhagic fluid) or pulmonary hemorrhage,[508] and exhibit rapid clinical deterioration.

Although hemangiosarcoma may involve the thoracic cavity, the more common neoplasms include lymphoma and gastric squamous cell carcinoma.[326,511,512] Both tumors may be associated with the development of pleural effusion.

7.4.13.2 Clinical Signs

Horses with thoracic neoplasms may have a history of weight loss, inappetence, exercise intolerance, ventral edema, and intermittent fever. Depending on the tumor, physical examination may or may not reveal signs referable to the respiratory tract. In some cases, horses exhibited signs that were initially compatible with inflammatory airway disease, pleuropneumonia, and pulmonary epistaxis.[489,507,508] Hypertrophic pulmonary osteoarthropathy characterized by enlargement of the joints, bony swellings of the distal limbs, and generalized stiffness has been reported in cases of granular cell tumor.[513,514]

7.4.13.3
Diagnosis

Endoscopic examination may reveal the presence of masses occluding the bronchi, as in the case of primary granular cell tumors and bronchogenic carcinomata.[489,494] Pleuroscopy may reveal the extent of tumor involvement. Transtracheal aspirates, bronchoalveolar lavages, cytologic aspirates, histologic examination of biopsy specimens, and thoracocentesis may aid in the diagnosis. Radiographic or ultrasonographic evidence of multifocal interstitial densities (2 to 3 cm in diameter), tracheal elevation, or mediastinal densities also suggest neoplasms.

7.4.13.4
Treatment

The prognosis is poor for horses with neoplasms, and most patients are euthanized. In horses in which the tumor is localized and has a low metastatic potential, as exists with granular cell tumors, lung resection may be an option.[515] In cases with malignant effusion, the clinician may achieve temporary stabilization by thoracocentesis and possibly with pleurodesis (see the section on pleural effusion). 341

8 CHAPTER 8 DISORDERS OF THE CARDIOVASCULAR SYSTEM

John D. Bonagura

Virginia B. Reef

Identification, evaluation, and treatment of the horse with cardiovascular diseases present a significant challenge to the veterinarian. Cardiovascular lesions are common in horses. Often these lesions are minor and well tolerated; however, cardiovascular disease can become clinically significant, manifesting as exercise intolerance, arrhythmia, weakness, systemic infection, congestive heart failure, or sudden death. Because the horse is a species renowned for its physiologic murmurs and arrhythmias, the cardiovascular findings may be confusing. Moreover, the effect of a cardiac lesion on a performance animal that depends so much on circulatory function can be difficult to quantify without a thorough examination.

Equine cardiology has advanced from a study of physiologic variation and speculation to one of accurate diagnosis and focused therapy. Much of the important groundwork in clinical equine cardiology can be attributed to the studies of Detweiler and colleagues[1–4]; Hamlin, Smith, and Smetzer, and their colleagues[5–20]; and Holmes and his graduate students.[21–51] The initial information these cardiologists provided about normal function, auscultation, and electrocardiography of the equine heart was accurate, and many still commonly make clinical decisions based on the data they provided. Because of the great size of the mature horse, traditional diagnostic studies such as radiography have played a smaller role in the assessment of heart diseases. Recent laboratory developments, including Holter electrocardiography, Doppler echocardiography, and functional exercise testing, have become increasingly important in assessing cardiovascular disease. These diagnostic studies allow detection and quantitation of a variety of anatomic and physiologic disturbances of the heart and circulation.

No comprehensive studies of cardiovascular *disease prevalence* have been done. Holmes observed that 2.5% of hospitalized horses were in atrial fibrillation.[33] Else and Holmes noted myocardial fibrosis in 14.3% of horses examined at necropsy and evidence of chronic valvular disease in approximately 25% of the hearts examined.[27–29] Various cardiovascular lesions were considered to be important in 8.5% of 480 consecutive losses in a necropsy study conducted by Baker and Ellis.[52] Cardiovascular diseases have been suggested to be the third most common cause of poor performance following musculoskeletal and respiratory diseases.[53–55] Occult heart disease, cardiac arrhythmias, and vascular lesions are important reasons for unexplained sudden death.[52,56–67] Certainly, most clinicians regularly encounter manifestations of cardiovascular disease or dysfunction.

Assessment of cardiovascular disease in a horse is predicated on a competent clinical examination and on the clinician' knowledge and ability to evaluate data from various diagnostic studies. Incomplete information may impede an accurate communication of risks to the client and delay a proper course of management. A review of the currently available information regarding the diagnosis and therapy of cardiovascular diseases is the focus of this chapter. The authors assume that the reader is familiar with basic cardiovascular anatomy, physiology, and electrophysiology, and these topics have been reviewed elsewhere.[9,20,68–74] The authors briefly describe pertinent aspects of clinical cardiac anatomy and physiology relevant to causes of equine heart diseases, review important studies essential in the diagnosis of cardiovascular disease, and have designed subsequent sections to provide the student and practicing 355
veterinarian with a framework for understanding the pathophysiology, clinical identification, and management of 356
important congenital and acquired conditions of the heart and major vessels. Instrumental to each discussion are clinically relevant aspects of diagnosis and therapy. Clinical aspects of circulatory shock are described in this volume, and the reader is referred elsewhere for the management of cardiopulmonary arrest.[75,76]

8.1 Anatomic Correlates Of Cardiovascular Diseases

Many diagnostic techniques, including cardiac auscultation, cardiac catheterization, and echocardiography, are predicated on an understanding of cardiac anatomy and physiology. Furthermore, the causes of cardiovascular disease can be subdivided into anatomic and physiologic (functional) diagnoses and into etiologic considerations (Boxes 8-1 and 8-2).

The cardiovascular system is divided into two separate circulations: systemic and pulmonary. The systemic circulation has a greater venous capacity, ventricular pumping pressure, arterial pressure, and vascular resistance.[70,73] Despite these differences, the functions of these two circulations are intertwined. Systemic and pulmonary circulations are arranged in series; therefore disordered function of either side can affect the contralateral circulation. Cardiac output (CO) from the left ventricle must be equal to that of the right ventricle, because ventricular filling depends on venous return from the contralateral circulation. Isolated left ventricular (LV) failure increases pulmonary venous pressure. The resultant pulmonary hypertension imparts a pressure load on the right ventricle and is a common cause of right ventricular (RV) failure. Leftward bulging of the ventricular septum, following RV dilation, can impair filling of the left ventricle.

The heart consists of various active and passive components[73]; therefore different methods and techniques are necessary to evaluate these structures and their associated functions. For normal heart action to proceed, coordination of electric activity, muscular contraction and relaxation, and valve motion must occur. When one reviews heart anatomy, and subsequently cardiac pathology, considering the normal development of the heart and the anatomic integrity of the pericardium, myocardium, endocardium and valves, specialized impulse-forming and conduction systems, and blood vessels is useful.[74]

8.1.1 PERICARDIAL DISEASE

The pericardium limits cardiac dilation, acts as a barrier against contiguous infection, and contributes to the diastolic properties of the heart. The pericardial space is formed by the reflection of the two pericardial membranes, the parietal pericardium and the visceral pericardium (the epicardium), and normally contains such a small amount of serous fluid that echocardiography cannot detect the fluid. Pericardial effusion, tamponade, and 356
constriction can decrease ventricular filling and diastolic function greatly. Pericardial diseases, as well as mass 358
lesions impinging on the systemic veins or the heart, can lead to right-sided congestive heart failure (CHF).

8.1.1.1 BOX 8-1 CARDIAC DIAGNOSES

8.1.1.1.1 Anatomic Diagnosis

Cardiac malformation

Valvular (endocardial) disease

Myocardial disease

Pericardial disease

Cor pulmonale (pulmonary disease leading to secondary heart disease)

Disorder of the impulse-forming or conduction system

Vascular disease

8.1.1.1.2

Physiologic Diagnosis

Systemic: pulmonary shunting

- Left to right
- Right to left

Valvular insufficiency

Valvular stenosis

Myocardial (systolic) dysfunction

Diastolic dysfunction

Cardiac rhythm disturbance

Cardiac-related syncope

Heart insufficiency or failure (limited cardiac output)

Congestive heart failure

Shock

Sudden cardiac death

Cardiopulmonary arrest

8.1.1.1.3

Etiologic Diagnosis

Malformation (genetic)

Degenerative disease

Metabolic or endocrine disease

Neoplasia

Nutritional disorder

Inflammatory disease

- Infective or parasitic

- Noninfective
  - Immune-mediated
  - Idiopathic
- Ischemic injury
- Idiopathic disorder
- Iatrogenic disease
- Toxic injury
- Traumatic injury

8.1.1.2 BOX 8-2 CAUSES OF CARDIOVASCULAR DISEASE

8.1.1.2.1 Congenital Cardiac Malformation

- Simple systemic-to-pulmonary shunts (left to right)
  - Atrial septal defect
  - Ventricular septal defect
    - Paramembranous defect
    - Ventricular inlet defect
    - Subarterial defect
    - Muscular defect
  - Patent ductus arteriosus
- Patent foramen ovale (permitting right-to-left shunting)
- Valvular dysplasia
  - Pulmonic stenosis (bicuspid pulmonary valve)

Pulmonary atresia (leading to a right-to-left shunt)

Tricuspid stenosis/atresia (leading to a right-to-left shunt)

Aortic stenosis/insufficiency (bicuspid or quadricuspid valve)

Subaortic rings with stenosis

Tetralogy of Fallot

Pulmonary atresia with ventricular septal defect (pseudotruncus arteriosus)

Double-outlet right ventricle

Subaortic stenosis

Hypoplastic left-side of the heart

Other complex malformations

8.1.1.2.2 Valvular Heart Disease Causing Valve Insufficiency or Stenosis

Congenital valve malformation

Semilunar valve fenestrations causing valve insufficiency

Degenerative (fibrosis) or myxomatous disease causing valve insufficiency

Vavular prolapse

Bacterial endocarditis causing valve insufficiency with or without stenosis

Rupture of a chorda tendinea causing mitral or tricuspid valve insufficiency

Rupture of a valve leaflet causing flail leaflet and valve insufficiency

Noninfective valvulitis

Valvular regurgitation following dilation of the heart or a great vessel

Papillary muscle dysfunction causing valvular insufficiency

8.1.1.2.3 Myocardial Disease

Idiopathic dilated cardiomyopathy: ventricular dilation and myocardial contractility failure

Myocarditis

Myocardial fibrosis

- Ischemic (embolic?) myocardial fibrosis
- Parasitic *(Strongylus)* embolization

Myocardial degeneration/necrosis

- Toxic injury (e.g., monensin)
- Nutritional deficiencies (e.g., selenium deficiency)

Myocardial neoplasia

- Lymphosarcoma
- Melanoma
- Hemangioma/hemangiosarcoma
- Pulmonary carcinoma

Infiltrative myocardial disease (e.g., amyloidosis)

8.1.1.2.4

Pericardial Disease

Pericardial effusion with or without cardiac tamponade

- Infective: bacterial or viral
- Idiopathic pericardial effusion
- Constrictive pericardial disease
- Mass lesion (intrapericardial or extrapericardial) compressing the heart

8.1.1.2.5

Pulmonary Hypertension and Cor Pulmonale

Pulmonary hypertension following left-sided heart disease

Pulmonary vascular disease following left-to-right shunt

Immature pulmonary circulation

Primary bronchopulmonary or pulmonary vascular disease

Alveolar hypoxia with reactive pulmonary arterial vasoconstriction

Severe acidosis

Pulmonary thromboembolism

8.1.1.2.6

Cardiac Arrhythmias (see Box 8-9)

Atrial arrhythmias

Junctional (nodal) arrhythmias

Ventricular arrhythmias

Conduction disturbances

8.1.1.2.7

Vascular Diseases

Congenital vascular lesions

Rupture of the aorta, pulmonary artery, or systemic artery

Aneurysm of the aortic sinus of Valsalva

Aortic or aortoiliac degenerative disease

Arteritis

- Infective
- Immune-mediated

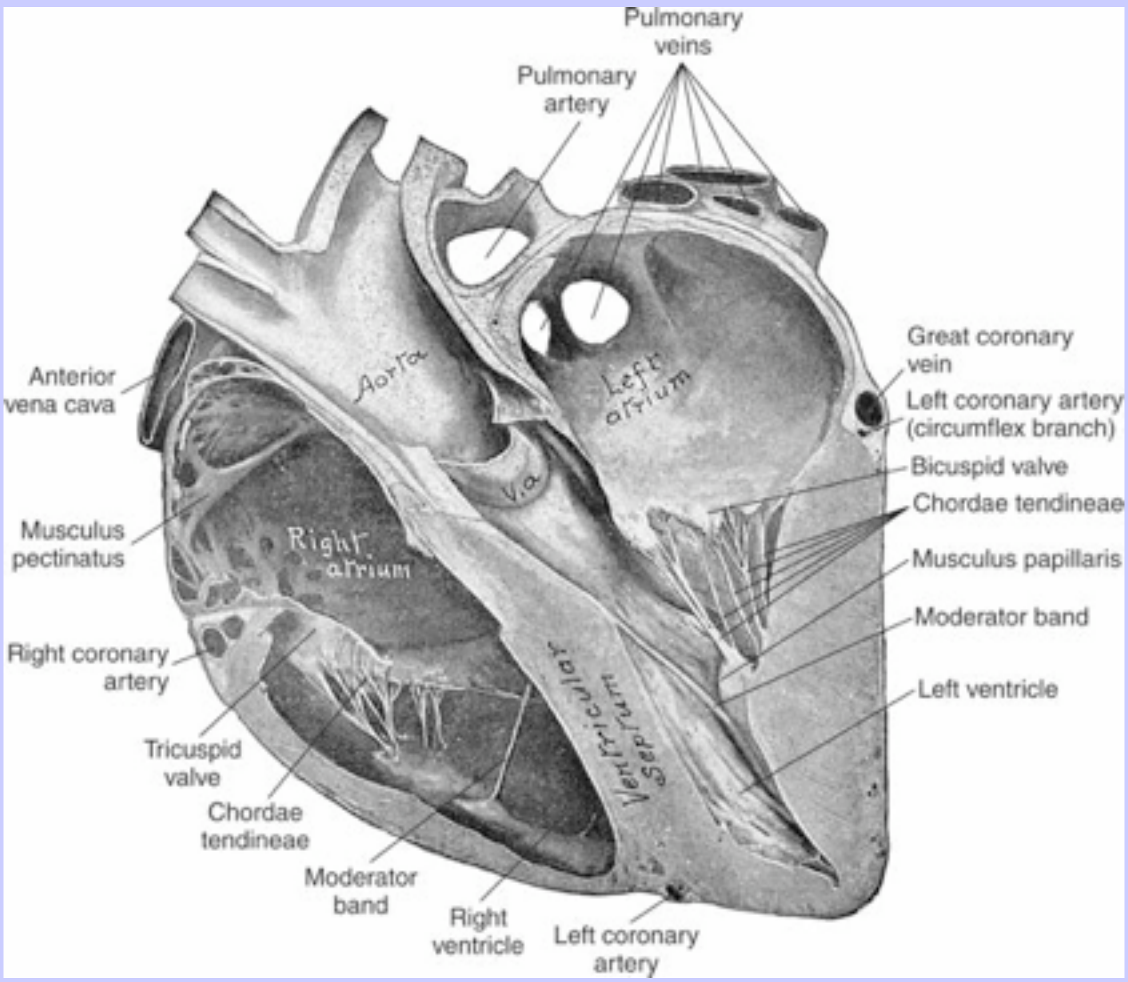
Thrombophlebitis

Pulmonary embolism

Mass lession or tumor obstructing blood flow

Pericardial effusion can develop as a primary disorder or following pleuropneumonia. Infective pericarditis can produce an effusion sufficient to cause cardiac tamponade or eventual constriction of the heart.[55,77–91] Sterile, idiopathic pericardial effusion also has been reported in horses. The volume of effusion can be substantial and can lead to cardiac decompensation.[84] Cardiac mass lesions and intrapericardial tumors have been reported sporadically.[86,89,92,93] Cranial mediastinal tumors (lymphosarcoma) or abscesses following pleuropneumonia also can compress the heart and mimic pericardial disease.[94] Clinical aspects of pericardial disease are discussed later in this chapter.

Figure 8-1 Sagittal view of the equine heart. The thicknesses of the ventricles, the position of the atria relative to the ventricles, and the relationship of the left ventricular inlet and outlet are evident. The bicuspid valve referred to in this figure is the mitral valve. The circular appearance of the left atrium and the relationship of the septal cusp of the mitral valve to the left ventricular inlets and outlets are notable. These aspects are important when examining the heart by echocardiography. *v.a.,* Segment of aortic valve. (From Sisson S, Grossman JD: *Anatomy of the domestic animals,* ed 4, Philadelphia, 1953, WB Saunders.)



8.1.2 MYOCARDIAL DISEASE

The myocardium forms the bulk of the atrial and ventricular muscular walls. The right atrium, which is larger than the left atrium, communicates with the RV inlet through the right atrioventricular or tricuspid valve. The right ventricle, appearing crescent-shaped on cross-sectional echocardiographic studies, is functionally U-shaped with the inlet at the right hemithorax and the outlet, pulmonary valve, and main pulmonary artery located on the left side of the chest. The thicker (by approximately 2.5 to 3 times) ventricular septum and attached LV wall is circular in cross section when viewed by echocardiography and is functionally V-shaped with an inlet and outlet separated by the cranioventral (septal or anterior) leaflet of the left atrioventricular, or mitral, valve (Figure 8-1). 358
The aorta originates in the LV outlet, continuous with the ventricular septum cranially and the septal mitral 359
leaflet caudally, and exits from the center of the heart and to the right of the main pulmonary artery. Ventricular or atrial dilation are recognized by echocardiography or at necropsy by distention and rounding of the affected chambers. Persistent embryologic openings in the cardiac septa are known as septal defects, with the ventricular septal defect (VSD) representing the most common cardiac anomaly in most practices (see Box 8-2).

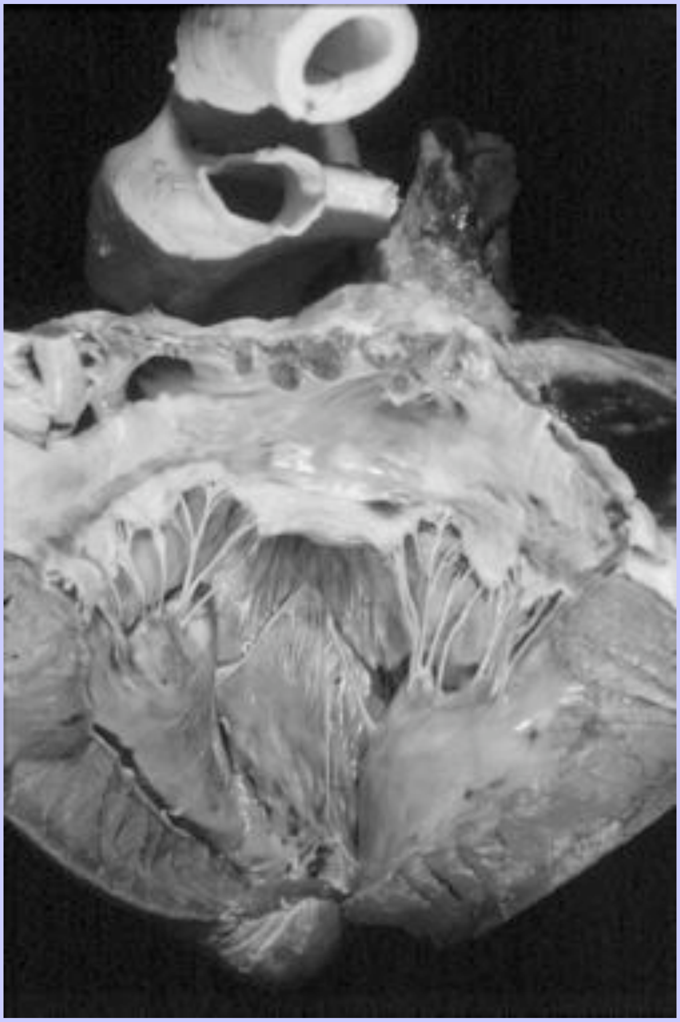
The myocardium may dilate or hypertrophy in response to exercise,[95] increased work caused by structural cardiac disease, or as a result of a noncardiac disorder. Lesions causing systolic pressure overload lead to concentric hypertrophy.[96] More common are lesions such as incompetent valves that cause ventricular volume overload with dilation and eccentric ventricular hypertrophy. Increased cardiac work also occurs in response to exercise, severe anemia, and infections. In these situations, compensatory increases in CO, sympathetic activation, and peripheral vasodilation occur to maintain oxygen delivery to the tissues.[97,98]

The overall prevalence of myocardial disease is unknown; however, multifocal areas of fibrosis commonly are found at necropsy.[28,29,99–102] Whether these areas indicate prior inflammation, toxic injury, or ischemic necrosis caused by intramural coronary disease is uncertain. Cases of multifocal or diffuse myocarditis have been observed. Myocardial inflammation and myocardial failure can lead to cardiac arrhythmias and heart failure.[3,103,104] Idiopathic dilated cardiomyopathy develops sporadically and is recognizable by echocardiography or nuclear studies as a dilated, hypokinetic left or right ventricle.[87,105] Ingestion of monensin can cause mild to severe myocardial injury.[106–111] Neoplastic infiltration is considered rare.[58,92,93,112] Myocardial contraction is dictated by electric activity of the myocardium; accordingly, cardiac arrhythmias, especially atrial fibrillation, can limit CO and cause exercise intolerance in performance animals (see the following discussion). Clinical aspects of myocardial disease are discussed later in this chapter.

8.1.3 VALVULAR AND ENDOCARDIAL DISEASES

The endocardium lines the cardiac chambers, covers the four cardiac valves, and is continuous with the endothelium of the great vessels. Normal valves govern the one-way flow of blood in the heart by preventing regurgitation of blood from higher to lower pressure zones. The atrioventricular inlet valves, the tricuspid and the mitral, are anchored by the collagenous chordae tendineae and papillary muscles and are supported by a valve "annulus" and the caudal atrial walls (see Figures 8-1 and 8-2).[74] The mitral valve consists of two major cusps and several accessory cusps.[45] The tricuspid valve is the largest valve and consists of three well-defined leaflets. Lesions of any portion of the atrioventricular valve apparatus or dilation of the ventricle can lead to valvular insufficiency (see Box 8-2). The aortic and pulmonary valves each consist of three leaflets that close during diastole to protect the ventricles from the higher arterial blood pressures. The left and right main coronary arteries originate within the aortic valve sinuses (of Valsalva).

Figure 8-2 Anatomy of the left atrioventricular (mitral) valve. Opened left atrium and left ventricle viewed from the caudal perspective. The large anterior (cranioventral or septal) leaflet in the center of the figure is notable. Chordae tendineae attach the valve to the papillary muscles. The ventricle has been cut so that the multiple cusps of the posterior (caudodorsal or mural) leaflet are visible to the left and the right of the anterior leaflet.



Valvular disorders are common.[*] Congenital valve stenosis, dysplasia, or atresia occur sporadically in foals. Degenerative diseases of the aortic, mitral, and tricuspid valves are common in mature horses,[3,103,116,145–158] and endocarditis can develop on any cardiac valve[†] (see Box 8-2). Valvular lesions of obscure cause, including nonseptic valvulitis, have been recognized sporadically. Tricuspid regurgitation, of unknown cause, often is

detectable in high performance animals, including Standardbred and National Hunt horses.[162,163] Mitral regurgitation (MR) caused by rupture of a chorda tendinea is common and has been observed in foals and mature animals.[38,122,137,164] Clinical aspects of valvular heart disease are discussed later in this chapter.

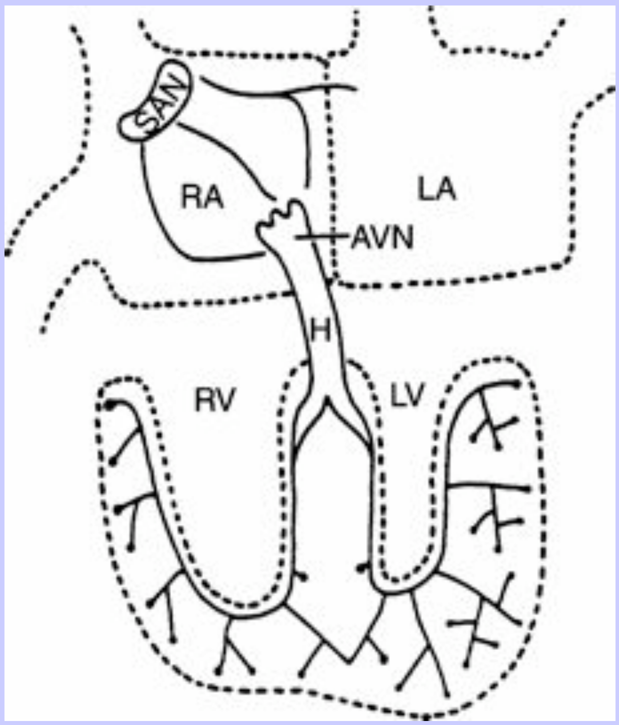
360

8.1.4 DISEASE OF THE IMPULSE-FORMING AND CONDUCTION SYSTEMS

The specialized cardiac tissues consist of the sinoatrial node, internodal pathways, atrioventricular node, bundle of His, bundle branches, fascicles, and Purkinje system (Figure 8-3). The sinoatrial node is a large, crescent-shaped structure located subepicardially at the junction of the right auricle and cranial vena cava. Well-documented sinus node disease, although suggested,[165] is rare; in contrast, vagally induced sinus arrhythmias are common.[9,165–167] The equine atrial muscle mass is large and predisposes the horse to develop reentrant rhythms and atrial fibrillation.[168] The atrioventricular node, situated in the ventral atrial septum, and the bundle of His, which continues on into the bundle branches, are sites for atrioventricular block, physiologic (vagal) and infrequently pathologic. Conduction is slow across the atrioventricular node.[169–171] The His-Purkinje system in the ventricular septum and ventricular myocardium can act as substrates for junctional and ventricular ectopic impulses and tachycardias. Because the horse has relatively complete penetration of Purkinje fibers to the ventricular free walls, except for a small portion of the LV free wall, the substantial equine ventricles are activated electrically in a short time (~110 ms).[7]

The autonomic nervous system extensively innervates the heart and influences cardiac rhythms.[3,103,124,172–177] Interplay between the sympathetic and parasympathetic branches normally controls heart rate and rhythm in response to changes in arterial blood pressure.[9,178] The vagus innervates supraventricular tissues extensively and probably affects proximal ventricular tissues to a minor extent. Vagal influence is generally depressive to heart rate, atrioventricular conduction, excitability, and myocardial inotropic (contractile) state. However, because vagotonia shortens the action potential and refractory period of atrial myocytes, high vagal activity may be a predisposing factor in the development of atrial fibrillation.[179] Innervation of the stimulatory sympathetic nervous system is extensive throughout the heart and has effects opposite to those of the parasympathetic system. β_1-Adrenergic receptors dominate in the equine heart,[180] but presumably other autonomic subtype receptors include α-adrenergic receptors and possibly small numbers of β_2-adrenoceptors.[181] The notable increase in heart rate that attends exercise is related to increased sympathetic efferent activity and withdrawal of parasympathetic tone.[9] Increases in heart rate to 220 to 240 beats/min are common with maximal exercise.[182–186] The exact role of dysautonomia in the genesis of cardiac arrhythmias has not been determined; however, infusion of autonomic receptor agonists and antagonists can be associated with direct or baroreceptor-induced changes in heart rate and rhythm.[187–190] Cardiac arrhythmias are discussed later in this chapter.

Figure 8-3 Schematic demonstrating the anatomy of the impulse-forming and the conduction system. Diagram shows the sinoatrial node *(SAN)*, right atrium *(RA)*, left atrium *(LA)*, atrioventricular node *(AVN)*, bundle of His *(H)*, and the bundle branches continuing into the Purkinje system in the right ventricle *(RV)* and the left ventricle *(LV)*. (Courtesy Robert L. Hamlin.)



8.1.5

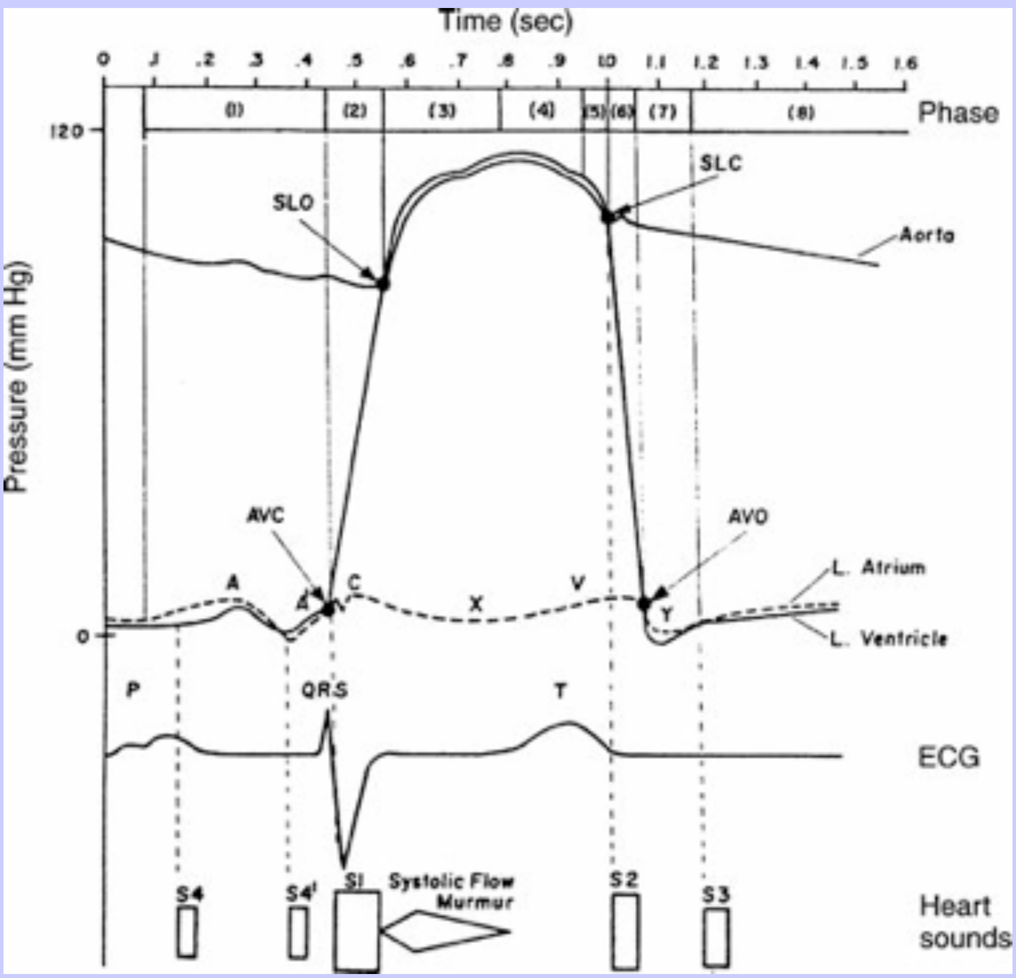
VASCULAR DISEASES

The arteries and veins consist of three layers: adventitia, media, and intima. The overall structure and function of each layer varies with the vessel and location. Vascular receptors[20,70,73,181] and anatomic lesions influence vascular resistance and blood flow. α-Adrenoceptors dominate in the systemic vasculature, and blood pressure generally increases by vasoconstriction following stimulation of postsynaptic α-adrenergic receptors by norepinephrine, epinephrine, or infused α-adrenergic receptor agonists such as phenylephrine.[191,192] The presence of vasodilator β_2-adrenergic receptors is clinically relevant, insofar as infused β_2-agonists cause vasodilation in circulatory beds that contain high β-agonist adrenergic receptor density. Many vascular beds also dilate following the production of local vasodilator substances, such as nitric oxide, released during exercise, stress, or metabolic activity.[70,73] Dopaminergic receptors, when present in vascular walls, may be stimulated to cause vasodilation, provided vasoconstricting α-adrenergic activity does not dominate. Stimulation of $histamine_1$ receptors or serotonin (5-hydroxytryptamine) receptors causes arteriolar dilation, venular constriction, and increased capillary permeability.[73] Infusion of endothelin[193] or of calcium salts causes arterial vasoconstriction,

[194] whereas administration of calcium channel antagonists (e.g., verapamil and diltiazem) causes vasodilation of vascular smooth muscle. 360

361

Figure 8-4 The cardiac (Wiggers') cycle of the horse. This drawing integrates the electric, pressure, mechanical, and flow events of diastole and systole and demonstrates the origins of the heart sounds. Electric activity precedes mechanical events. See the text for a full description. *AVC,* Closure of the mitral (atrioventricular) valve; *AVO,* opening of the mitral (atrioventricular) valve; *SLO,* opening of the aortic (semilunar) valve; *SLC,* closure of the aortic (semilunar) valve. (Modified from Detweiler DK, Patterson DF: The cardiovascular system. In Cattcott EJ, Smithcors JF, editors: *Equine medicine and surgery*, ed 2, Santa Barbara, Calif, 1972, American Veterinary Publications.)



Various vascular lesions have been reported (see Table 8-2). Rupture of the aorta, pulmonary artery, or middle uterine artery is devastating and typically lethal.[*] Although parasitic arteritis may predispose horses to vascular injury, the cause of most vascular lesions, including aortic-iliac thrombosis, is unknown.[197–202] Causes of vasculitis include *Strongylus vulgaris* infestation of the cranial mesenteric artery, infective thrombophlebitis of the jugular veins, equine viral arteritis, and suspected immune-mediated disease.[99,101,203] Clinical features of vascular disease are discussed later in this chapter.

* References 3, 34, 57, 103, 142, 195, 196.

8.2 Clinical Cardiovascular Physiology

The clinician must appreciate elementary aspects of normal heart function to understand changes in the pulses and auscultation and hemodynamic alterations that develop in heart disease and CHF.[204] Central to this understanding are the electric-mechanical correlates of Wiggers' cardiac cycle.[181]

8.2.1 CARDIAC CYCLE

The association between electric and mechanical events of the heart first described by Wiggers has been reviewed in standard physiology textbooks (Figure 8-4).[70,73,181] A study of this cycle gives evidence that cardiac electric activity precedes pressure and volume changes; therefore arrhythmias can have deleterious hemodynamic effects, especially during exercise, illness, or anesthesia. Understanding the cardiac cycle and considering the interrelated events during the course of an examination provides the clinician with critical information regarding cardiac rhythm and the health of the heart. Relevant aspects of this cycle are considered next.

The P wave of the electrocardiogram (ECG) results from electric activation of the atria late in ventricular diastole 361
and after the ventricles have filled passively. The ensuing atrial contraction generates the *atrial sound* (S_4), and 362
the ventricle fills to a slightly greater extent (termed the *end-diastolic volume*). The increase in atrial pressure, the atrial *a wave,* is reflected up the systemic venous system, causing a normal *jugular pulse* in the ventral cervical region. The magnitude of the atrial contribution to ventricular filling is greatest at high heart rates; therefore atrial tachyarrhythmias such as atrial fibrillation have a most serious effect during exercise.

The QRS complex heralds ventricular systole. After depolarization of the ventricular myocytes, calcium enters the cell to trigger shortening of the myofilaments and develop tension, an event that digitalis glycosides or catecholamines such as dobutamine can enhance. These changes lead to an abrupt increase in ventricular wall tension and intraventricular pressure. The atrioventricular valves close once atrial pressure is exceeded (generating the high-frequency *first heart sound,* S_1), the intraventricular pressure increases *(isovolumetric period),* and subsequently the semilunar valves open.[23,25] At this instant the ventricular walls move inward 362
(Figure 8-5) and eject blood into the great vessel (Figure 8-6). The contracting heart twists slightly during 363
systole, and the left ventricle strikes the chest wall caudal to the left olecranon, causing the *cardiac impulse* or apex beat. This early systolic movement, coincident with opening of the aortic valve, is a useful timing clue for cardiac auscultation. The delay between the onset of the QRS and the opening of the semilunar valves, termed the *preejection period,* is measurable by echocardiography and is an index of ventricular myocardial contractility such that positive inotropic drugs shorten the preejection period.[46,205–212] Blood is ejected into the pulmonary and systemic arteries with an initial velocity that generally peaks near 1 m/sec and is measurable by Doppler

echocardiography.[139,205] The aortic ejection time usually exceeds 400 ms in a horse at rest, and reductions of ejection velocity or ejection time suggest reduced LV function. A *functional systolic ejection murmur* often is audible during ejection. Such murmurs, by definition, must begin after the first sound and end before the second sound. One can palpate the *arterial pulse* during systole, but the actual timing of the pulse depends on the proximity of the palpation site to the heart. At the end of the *ejection period,* as ventricular pressures fall below those of the corresponding arteries, the semilunar valves close, producing the high-frequency *second heart sounds* (S_2) and the incisura of the arterial pressure curves.[19,23,25] The pulmonary valve may close after or before the aortic valve.[3,4,213] Asynchronous valve closure may lead to audible splitting of S_2, which is normal but can be extreme in some horses with lung disease. During the ejection period, the ventricular volume curve graphs a considerable reduction from the end-diastolic volume: this volume ejected is defined as the *stroke volume*. The ratio of the stroke volume to the end-diastolic volume is the *ejection fraction,* a commonly used index of systolic heart function. The ejection fraction commonly is estimated by echocardiography. Contraction of the ventricles causes the atrial pressures to decline, leading to the x descent of the atrial pressure curve and a brief systolic collapse of the jugular vein. Following atrial filling during ventricular systole, a positive pressure wave, the v wave, occurs in the atrial pressure curves. Severe tricuspid regurgitation (TR) accentuates this wave and may lead to pathologic systolic pulsations in the jugular furrow. Finally, a decline in ventricular pressure (isovolumetric relaxation) related to active ventricular relaxation and closure of the semilunar valves occurs.

Figure 8-5 Ventricular function and echocardiography. **A,** Derivation of the M-mode echocardiogram. The lines demonstrate typical paths of M-mode recording planes. (*1,* Ventricular/papillary muscle; *2,* chordae tendineae; *3,* anterior mitral valve *[AMV]*; *4,* aortic root and left atrium/auricle; *TW,* thoracic wall; *RVW,* right ventricular wall; *RV,* right ventricle; *S,* septum; *LV,* left ventricle; *AV,* aortic valve; *AO,* aortic outflow tract; *LVW,* left ventricular wall; *PMV,* posterior mitral valve; *LA,* left atrium) **B,** The drawing demonstrates the appearance of the M-mode echocardiogram at each level. (*PER,* Pericardium; *RS, LS,* right and left sides of the ventricular septum; *EN,* endocardium.) **C,** M-mode echocardiogram demonstrating the method of measuring left ventricular shortening fraction *(LVSF),* in which *D* is diastolic dimension and *S* is systolic dimension (LVSF = D – S/D). The prominent thickening of the walls during systole is notable. The end-systolic excursion of the left ventricular wall is visible *(arrow)*. In practice the systolic dimensions of the ventricular septum and the left ventricular wall generally are measured along the same line as demonstrated for the left ventricular lumen in systole *(S)*. (*W,* Left ventricular wall; *VS,* ventricular septum.)

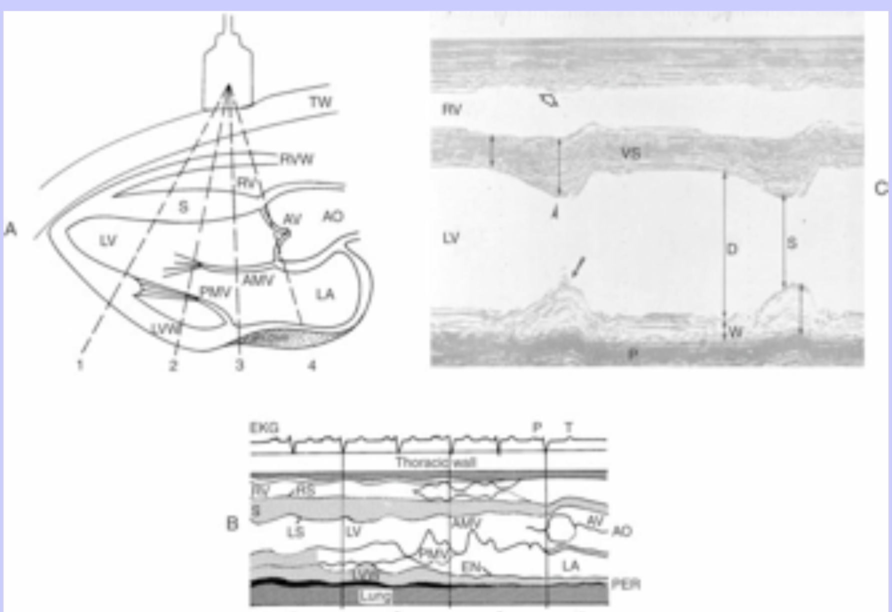


Figure 8-6 Compressed electrocardiogram *(ECG)* with simultaneous arterial blood pressure *(ABP)* recording in a horse with second-degree atrioventricular block. The progressive increase in arterial blood pressure triggers a baroreceptor reflex leading to atrioventricular conduction block *(upper arrows)* and a corresponding fall in the arterial blood pressure *(lower arrows)*. Presumably this mechanism, along with sinus arrhythmia and sinus arrest, represent vagally induced mechanisms for controlling arterial blood pressure in the standing horse.

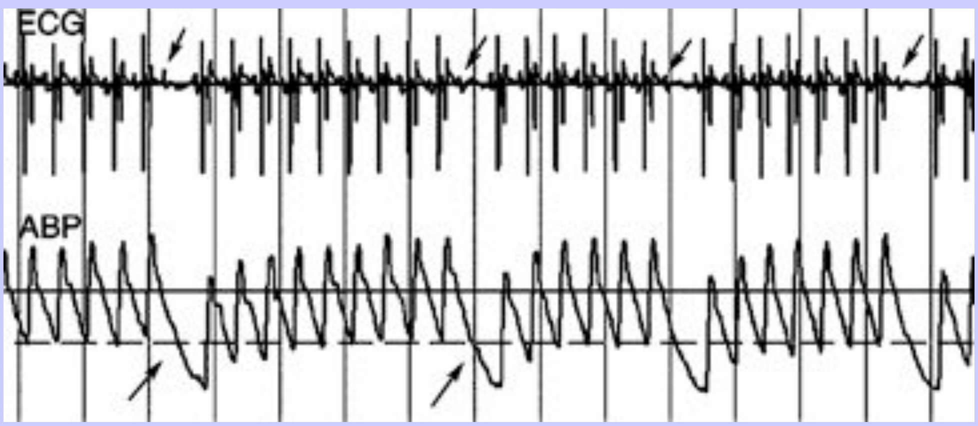

Filling commences just as the atrioventricular valves open. Ventricular diastole can be subdivided into three general phases: rapid ventricular filling, diastasis, and atrial contraction.[70,73,181] These phases are readily observable using pulsed wave Doppler echocardiography (see Figure 8-6). Once the ventricles have relaxed and the atrial pressure exceeds the corresponding ventricular pressure, the atrioventricular valves open. At that instant, rapid filling ensues with a peak velocity of about 0.5 to 1 m/sec, but varying directly with the heart rate.[139] The ventricular pressures increase only slightly during this phase, whereas the ventricular volume curves change dramatically from the venous return. Rapid filling may be associated with a *functional protodiastolic murmur,* which is concluded by the *third heart sound* (S_3), the low-frequency vibrations caused by termination of rapid ventricular filling. The loss of atrial volume and corresponding decline in the atrial pressure (the y descent) is reflected in the jugular furrow as the vein collapses. Following rapid filling, a period of greatly reduced low-velocity filling, diastasis, ensues. This period may last for seconds during sinus bradycardia or pronounced sinus arrhythmia, and with greatly exaggerated pauses the jugular vein may begin to fill prominently. The last phase of diastole is the contribution to ventricular filling caused by the atrial contraction. A functional *presystolic murmur* has been associated with this period between S_4 and S_1.

8.2.2

ASSESSMENT OF VENTRICULAR FUNCTION

The ability of the ventricles to eject blood depends on systolic and diastolic ventricular function and on heart rate and rhythm (Box 8-3). The most commonly used measurements of overall ventricular performance and

circulatory function are invasively or noninvasively determined arterial blood pressure, rate of ventricular pressure change, CO, stroke volume, ejection fraction, LV shortening fraction, central venous pressure, pulmonary artery or wedge pressures, and arteriovenous oxygen difference.[13,24,26,47,214–227] CO, the amount of blood pumped by the left (or right) ventricle in 1 minute (liters per minute), is the product of ventricular stroke 363
volume (milliliters per beat) multiplied by the heart rate (beats per minute). Cardiac index refers to the CO divided by (indexed to) the body surface area. CO coupled with systemic vascular resistance determines the mean arterial blood pressure: an increase in either variable raises mean arterial pressure. Values for CO vary widely with the size and activity of the horse and often are influenced by drug therapy or anesthesia.[188,228–239] One also can obtain a noninvasive estimate of CO using Doppler techniques.[208–210,225,240–248] 364

8.2.2.1
BOX 8-3 DETERMINANTS OF CARDIAC FUNCTION

8.2.2.1.1
Systolic Function: Determinants of Ventricular Stroke Volume

Preload [+]—ventricular end-diastolic volume

- Determinants of diastolic function (see below)
- Plasma volume
- Venous pressure/venous return

Myocardial inotropism [+]—contractility of the myocardium

- Sympathetic activity
- Myocardial disease
- Drugs (positive or negative inotropic agents)
- Myocardial perfusion

Ventricular afterload [–]—wall tension required to eject blood

- Aortic impedance
- Vascular resistance
- Ventricular volume (tension increases with dilation)
- Ventricular wall thickness (thin walls have higher tension)

Cardiac lesions increasing workload [–]

Valvular regurgitation (common)

Valvular stenosis (rare)

Septal defects and shunts

8.2.2.1.2

Diastolic Function: Determinants of Ventricular Filling

Pleural/mediastinal factors (pressure, mass lesions)

Pericardial function (intrapericardial pressure, constriction)

Myocardial relaxation

Myocyte stiffness

Ventricular wall distensibility (chamber and myocyte compliance)

Venous pressure and venous return (must be matched with compliance)

Heart rate and ventricular filling time (shortened by tachycardia)

Myocardial perfusion (ischemia impairs relaxation)

Atrial contribution to filling (lost in atrial fibrillation)

Cardiac rhythm (arrhythmias can alter atrioventricular contraction sequencing)

Atrioventricular valve function

8.2.2.1.3

Cardiac Output

Cardiac output = Stroke volume [+] × heart rate [+]

8.2.2.1.4

Arterial Blood Pressure

Arterial blood pressure = Cardiac output [+] × vascular resistance [+]

Ventricular stroke volume depends on myocardial contractility and loading conditions (preload and afterload).[24,26] Although traditionally considered to be independent determinants of myocardial function, these variables are interconnected and influence force, velocity, and duration of ventricular contraction.[181] Ultimately, the availability of calcium to the sarcomere is modulated by the inotropic state, the initial myocardial stretch (preload), and the tension that must be generated to eject blood into the vascular system (afterload).

Catecholamines, calcium, digitalis glycosides, and phophodiesterase inhibitors increase myocardial contractility.[*] Contractility is difficult to measure in the clinical setting, but one can estimate it by observing directional changes in ejection or shortening fractions (which are also load dependent) or by Doppler echocardiographic techniques including preejection period, ejection time, aortic acceleration, and velocity time integral (see Figure 8-5). Assessment of global LV performance commonly is accomplished clinically using M-mode and two-dimensional echocardiography.[266–270] Physiologic state, altered mildly by day-to-day variation[210,271] or sedatives,[206] influences measured variables, and general anesthesia greatly affects these variables.

Ventricular fiber length or preload is a positive determinant of ventricular systolic function that depends on venous return and ventricular size and distensibility. The normal ventricle depends greatly on preload so that an increase in preload increases stroke volume. Dehydration, venous pooling, loss of atrial contribution to filling (atrial fibrillation), and recumbency reduce ventricular filling and decrease stroke volume. When the horse develops hypotension resulting from decreased ventricular filling, the clinician usually administers intravenous crystalloid to increase venous pressure and preload. One can observe increased ventricular preload in horses with heart disease. Moderate to severe valvular insufficiency and CHF increase ventricular filling pressure and preload.[38,98,272,273] The increased ventricular diastolic dimension serves as a compensatory mechanism that 364
maintains forward stroke volume in the setting of a failing ventricle or regurgitant heart valve. 365

One can estimate ventricular preload by determining ventricular end-diastolic volume or size, as measured by echocardiography or by measuring venous filling pressures.[273] The measurement of venous filling pressures (central venous pressure, pulmonary diastolic or wedge pressure) provides an accurate gauge of preload provided that ventricular compliance (distensibility) is normal and ventilation is stable. Myocardial ischemia, which impairs myocardial relaxation, and pericardial diseases, which constrict the ventricles, reduce ventricular compliance; in such cases, the venous filling pressures may not reflect changes in ventricular preload accurately.

Ventricular *afterload* represents the tension that must develop in the ventricular walls before ejection of blood into the arteries. Increases in systemic arterial resistance, aortic blood pressure, and aortic impedance usually increase afterload and resist ventricular shortening. Increased afterload decreases stroke volume, unless ventricular force of contraction increases to compensate for the load. Afterload is difficult to measure clinically, and although systemic arterial blood pressure is not identical to afterload, it often is used to estimate directional changes in afterload. LV failure, alveolar hypoxia– induced pulmonary vasoconstriction, and atelectasis are important clinical causes of increased RV afterload. Arterial vasodilators such as hydralazine decrease LV afterload.[236]

Ventricular *synergy* refers to the normal method of ventricular activation and contraction. Normal electric activation causes a burst of activation of great mechanical advantage.[20] Cardiac arrhythmias, especially ventricular rhythm disturbances, can cause dyssynergy with a resultant decrease in stroke volume. Coronary occlusions leading to ischemic myocardial necrosis also cause dyssynergy but are rare.[56,101,274]

Structural and functional competency of the cardiac valves and ventricular septa influence ventricular systolic function. Valvular insufficiency or the rare obstruction may reduce ventricular stroke volume unless adequate compensation occurs from ventricular dilation and hypertrophy or heart rate reserve. For example, many septal defects are well tolerated at rest and during moderate exercise because of eccentric hypertrophy. However, large defects can lead to substantial shunting and volume overload of the left side of the heart, causing limited LV stroke volume, arrhythmias, or CHF.

Ventricular *diastolic function* determines ventricular filling and preload.[70,73,181,227] Box 8-3 indicates factors that affect diastolic function. When diastolic function is abnormal, heart rate dependency for maintenance of CO often is greater. A common cause of diastolic dysfunction is constriction or compression of the heart caused by pericardial disease. Arrhythmias affect ventricular diastolic function. Persistent tachycardia shortens diastole, cardiac filling time, and coronary perfusion. With atrial fibrillation the atrial contribution is lost. Junctional and ventricular arrhythmias prevent normal atrioventricular sequencing. Ventricular chamber dilation or hypertrophy decreases ventricular compliance and require higher ventricular distending pressures for filling. LV diastolic dysfunction resulting from severe RV dilation or hypertrophy can be explained by bulging of the ventricular septum into the left ventricle, which impedes filling of the left side. This effect occurs clinically with constrictive pericardial disease and severe pulmonary hypertension.

Objective measures of diastolic function are complicated, and no good clinical indicators of diastolic function are currently available. However, one may assume diastolic dysfunction on recognition of one of the aforementioned conditions. Measuring transmitral and tricuspid inflow using Doppler techniques is possible, but these methods are crude and also depend on atrial pressure. Tissue Doppler imaging can measure the actual velocity of myocardial wall segments in the equine heart and may provide insight into diastolic cardiac function.

Imbalance between *myocardial oxygen demand* and delivery can reduce ventricular systolic and diastolic function and may affect cardiac rhythm. Myocardial oxygen demand is augmented by increasing myocardial inotropic state, heart rate, and ventricular wall tension (related to preload and afterload).[181] Oxygen delivery depends on coronary anatomy and vasomotion (degree of vessel constriction), diastolic arterial blood pressure, diastolic (coronary perfusion) time, and metabolic activity of the myocardium.[10,73,275–282] Normal coronary flow to the LV myocardium is highest in the ventricular septum and LV wall.[282] The immediate subendocardial layer of myocardium is probably most vulnerable to ischemic injury,[9] and altered ventricular depolarization may develop following an imbalance in myocardial oxygen delivery. Depolarization may account in part for the ST segment to T wave depression and changes in the T waves observed in hypotensive animals and in normal horses during sinus tachycardia. Coronary vasomotion is effective in augmenting coronary perfusion even at high heart rates (up to 200 beats/min in ponies); however, coronary autoregulation is not as effective if diastolic perfusing pressure decreases in the aorta.[276,277,279]

The clinician may use the arterial blood pressure × heart rate "double product" as a general estimate of myocardial oxygen demand.[181] Persistent ST segment depression or elevation, especially at normal heart rates, suggests deficient myocardial perfusion.

365

366

8.3 Cardiovascular Examination

8.3.1 GENERAL APPROACH

Box 8-4 summarizes a general approach to recognizing and diagnosing heart disease and assessing its severity. Undoubtedly, history and auscultation are the most important initial evaluation procedures in the cardiovascular examination of the horse. With the exception of mild abnormalities in ventricular function, normal cardiac auscultation in a horse with good exercise tolerance practically precludes significant heart disease. The initial cardiovascular physical examination should include a thorough auscultation of the heart at all valve areas, auscultation of both lung fields, palpation of the precordium, evaluation of the arterial pulses (head and limbs),

inspection of the veins, and evaluation of the mucous membranes for pallor, refill time, and cyanosis, which may develop in foals following a right-to-left cardiac shunt. One also should record an accurate resting heart rate and respiratory rate.

A point of emphasis is that one can detect most *serious* cardiac disorders initially by physical examination and a stethoscope. One easily can discover sustained or recurrent cardiac arrhythmias through cardiac auscultation and palpation of the arterial pulse and can verify diagnosis of the rhythm through electrocardiography. Pericarditis and cardiac tamponade are characterized by muffled heart sounds or pericardial friction rubs, jugular distention, and often RV failure. Significant myocardial disease usually is associated with heart failure, arrhythmias, or a cardiac murmur, especially in advanced cases in which ventricular dilation causes secondary insufficiency of the mitral or tricuspid valves. The presence of a cardiac murmur is the essential finding that leads one to suspect degenerative or infective valvular disease or a congenital heart malformation.[103,146]

Laboratory studies, electrocardiography, and echocardiography are additional tests particularly useful in recognizing the underlying basis and severity of cardiovascular disease. Mild or subtle cardiovascular disease may require a detailed examination, including exercise testing,[283–288] before one can detect abnormalities objectively.

8.3.2 HISTORY

One may suspect cardiovascular disease from the history or a serendipitous finding during a routine examination.[*] One may examine the horse with CHF for obvious generalized venous distention, jugular pulsations, or edema. Conversely, other cardiac problems such as arrhythmia or murmur can be incidental findings, detected during a routine physical, prepurchase, or insurance examination. Once one finds an abnormality, a complete cardiovascular examination is aimed at determining the lesion and the significance of disease in terms of safety, performance capabilities, and expected longevity.

The horse with clinically apparent cardiovascular disease may have subtle performance problems that are apparent only at peak performance levels. Slowing in the last quarter to three eighths of a race is a common historical complaint. In many cases, performance may deteriorate by only 2 to 3 seconds. In other horses, particularly in cases of atrial fibrillation, racing performance may decline greatly by 20 to 30 seconds or more. Horses with malignant ventricular tachycardia may stop abruptly or even fall. Horses with cardiovascular disease may have excessively high heart and respiratory rates during and after exercise and may take longer than normal time to return to a resting rate. Such horses take longer to cool out. Coughing, at rest or during exercise, and exercise-induced pulmonary hemorrhage are reported in some horses with heart disease. One always must consider cardiovascular disease along with musculoskeletal, respiratory, metabolic, and neurologic problems in the differential diagnosis of poor performance (Box 8-5).[54,55,118,292] Other performance-related problems with cardiovascular disease can include weakness, ataxia, collapse, and sudden death[52,56–67,196] (Box 8-6).

* References 32, 103, 104, 174, 224, 289–291.

8.3.3 AUSCULTATION

8.3.3.1 Clinical Method

Auscultation is an accurate method for cardiac diagnosis, but effective auscultation requires an understanding of anatomy, physiology, pathophysiology, and sound. Clinical experience regarding cardiac auscultation in the

horse is extensive,[*] and recent experience with Doppler echocardiography has refined the clinician's understanding of heart sounds and murmurs.[120,135] Experience and training are also significant factors in effective cardiac auscultation,[307,308] and one should consider auscultation an acquired skill to be honed constantly. The overall sensitivity of auscultation for identification of congenital heart disease is high, as is the sensitivity for recognition of *significant* valvular disease and *persistent* cardiac arrhythmias. Sensitivity is probably lower for primary myocardial or pericardial diseases, unless associated abnormalities such as a murmur, arrhythmia, or prominent friction rub are obvious. The specificity of auscultation in the horse—for example, the ability to distinguish a functional from a pathologic murmur or identify a specific flow 366
disturbance—has not been sufficiently studied, but most certainly depends on the clinician's knowledge and 368
experience.[307]

8.3.3.1.1 BOX 8-4 CLINICAL EXAMINATION OF THE EQUINE CARDIOVASCULAR SYSTEM

8.3.3.1.1.1 History and Physical Examination[*]

Work history and identification of possible hemodynamic dysfunction

Heart rate and rhythm

Examination of the arterial and venous pulses, refill, and pressure

Inspection of the mucous membranes

Evaluation for abnormal fluid accumulation: pulmonary, pleural, peritoneal, and subcutaneous

Auscultation of the heart and lungs

Measurement of arterial blood pressure (indirect method)

8.3.3.1.1.2 Electrocardiography

Heart rate, rhythm, and conduction sequence

P-QRS-T complexes: configuration, amplitude, duration, and axis

Postexercise and exercise electrocardiography[†]

Holter (tape-recorded) electrocardiogram[†‡]

8.3.3.1.1.3 Echocardiography

M-mode echocardiography: cardiac dimensions and systolic ventricular function, cardiac anatomy and valve motion, and estimation of cardiac output

Two-dimensional echocardiography: cardiac anatomy and size, systolic ventricular function, identification of lesions, and estimation of cardiac output

Doppler echocardiography[‡]: identification of normal and abnormal flow, estimation of intracardiac pressures, estimation of cardiac output, and ventricular function

Postexercise echocardiography: identification of regional or global wall dysfunction or valve dysfunction exacerbated by exercise

8.3.3.1.1.4

Thoracic Radiography

Evaluation of pleural space, pulmonary parenchyma, and lung vascularity

Estimation of heart size (more beneficial in foals)

8.3.3.1.1.5

Clinical Laboratory Tests

Complete blood count and fibrinogen to identify anemia or inflammation

Serum biochemical tests including electrolytes, renal function tests, and muscle enzymes: These studies may be useful for assessing arrhythmias, identifying low cardiac output (azotemia), and recognizing myocardial cell injury (cardiac isoenzymes of creatine kinase or lactic dehydrogenase, troponin concentration)

Serum protein to identify hypoalbuminemia and hyperglobulinemia

Arterial pH and blood gas analysis to evaluate pulmonary and renal function and to assess acid-base status

Urinalysis to identify renal injury from heart failure or endocarditis

Blood cultures for bacteremia and diagnosis of endocarditis

Serum/plasma assays for digoxin, quinidine, and other drugs

8.3.3.1.1.6

Radionuclide Studies[§]

Detection of abnormal blood flow or lung perfusion and assessment of ventricular function

8.3.3.1.1.7

Cardiac Catheterization and Angiocardiography[§]

Diagnosis of abnormal blood flow and identification of abnormal intracardiac and intravascular pressures

* Most important part of the cardiac evaluation.

† May be needed to identify paroxysmal atrial fibrillation.

‡ Generally done after referral.

§ Not commonly performed.

Modified from Bonagura JD: Clinical evaluation and management of heart disease, *Equine Vet Educ* 2:31-37, 1990.

8.3.3.1.2

BOX 8-5 CARDIOVASCULAR ASSOCIATION OF POOR PERFORMANCE

8.3.3.1.2.1

Arrhythmias

Atrial premature complexes

Ventricular premature complexes

Atrial fibrillation

Supraventricular tachycardia

Ventricular tachycardia

Advanced second-degree atrioventricular block

Complete third-degree atrioventricular block

8.3.3.1.2.2

Congenital, Valvular, or Myocardial Heart Diseases Associated With Murmurs

Ventricular septal defect

Mitral regurgitation

Tricuspid regurgitation

Aortic regurgitation

Cardiomyopathy with secondary atrioventricular valvular regurgitation

8.3.3.1.2.3

Occult Heart Disease

Pericardial disease

Cardiomyopathy or myocarditis

Ischemic myocardial disease (?)

8.3.3.1.2.4

Vascular Disorders

Aortic-iliac thrombosis

Jugular vein thrombophlebitis

Aortic root rupture

Pulmonary artery rupture

A prerequisite for auscultation is an appreciation of the normal heart sounds, the genesis of which has been described already (Clinical Cardiovascular Physiology). The examiner must be familiar with the causes and clinical features of murmurs and arrhythmias (Tables 8-1 to 8-3) and the areas for auscultation (Figures 8-7 and 8-8).[*] Auscultation is best carried out in a quiet area because extraneous noise makes detection of soft to moderate murmurs difficult. The clinician should palpate the arterial pulse and the precordium before commencing auscultation and should use both stethoscope chest pieces: the diaphragm (applied tightly) and the bell (applied lightly).

8.3.3.1.3 BOX 8-6 CAUSES OF SUDDEN CARDIOVASCULAR DEATH

8.3.3.1.3.1 Electric Disorders of the Heart (Arrhythmias)

Ventricular tachycardia, flutter, or fibrillation

Complete atrioventricular block

Asystole

8.3.3.1.3.2 Toxic Injury to the Heart

Acute myocardial failure

Anesthetics

Drug- or toxin-induced arrhythmia

Toxic plants

Myocardial toxins

Systemic toxin secondarily affecting the heart

8.3.3.1.3.3 Cardiac Tamponade

Bacterial pericarditis

Idiopathic pericarditis

Viral pericarditis

Trauma

8.3.3.1.3.4 Hemorrhage

Rupture of the heart (with cardiac tamponade)

Rupture of the aorta or pulmonary artery (with or without cardiac tamponade)

Arterial rupture

Middle uterine artery

Mesenteric, omental, or other large arteries

Severe pulmonary hemorrhage

Rupture of the spleen or liver

Brain hemorrhage

8.3.3.1.3.5

Embolism

Carotid air embolism

Coronary embolism or thrombosis

8.3.3.1.3.6

Electrocution

Lightning

Alternating current electrocution

8.3.3.1.3.7

Cardiac Trauma

Cardiac catheterization or needle puncture of a ventricle leading to ventricular fibrillation

Penetrating thoracic wound

The clinician should examine all auscultatory areas and can identify the locations of the cardiac valve areas using the following method:

- The left thoracic wall cardiac impulse (left apical beat), located adjacent to or under the olecranon, identifies the ventral region of the LV inlet. Mitral sounds and murmurs usually project to this location 368
as well as radiating dorsally into the left atrium. S_1 is most audible at this location. 369
- The aortic valve area is located dorsally and one or two intercostal spaces cranial to the left apical impulse. S_2 is loudest at this point, and aortic murmurs are audible well over this valve. The murmur of MR also may radiate dorsally and cranially to this area.
- Because of the central location of the aortic valve and the dextrad orientation of the ascending aorta, aortic flow murmurs and the murmur of aortic regurgitation are audible bilaterally, just medial to the triceps muscles.
- The pulmonic valve is located slightly cranioventral (generally one intercostal space) to the aortic valve; the pulmonary component of S_2 is loudest at this point. Also at this location the splitting of S_2 is most obvious.

- The main pulmonary artery is dorsal to the pulmonic valve, high on the left base. Murmurs that radiate into the pulmonary artery are most audible at this location, including some functional murmurs and the murmur of patent ductus arteriosus. 369 370

- The tricuspid valve area is located over a wide area on the right hemithorax, dorsal to the sternum and just cranial to the mitral valve. Sounds and murmurs associated with tricuspid disease usually are most audible over the right hemithorax.

Concentrating first on the individual heart sounds when assessing the heart rhythm is worthwhile, because the generation of cardiac sounds depends on the underlying electric rhythm and heart murmurs are timed relative to the heart sounds. S_4 is audible after the P wave. S_1 and S_2 encompass systole, indicating the presence of a QRS complex. A murmur detected between S_1 and S_2 is termed *systolic*. In contrast, a murmur heard after S_2 is designated as *diastolic*. The distinctive S_4 is absent in arrhythmias such as atrial fibrillation. Normal variation in the P-R interval causes gradual changes in the S_4-S_1 interval. Absence of a QRS complex, which occurs with second-degree atrioventricular block (see Figure 8-6), causes a pause in which S_1 and S_2 are absent. One also can palpate the heart sounds and precordial movements, especially over the left thoracic wall. Frequently, one can detect the cardiac movements and low-frequency vibrations corresponding to the atrial contraction (S_4), onset of ventricular contraction (S_1), and closure of the semilunar valves (S_2). With ventricular volume overloading, an accentuated apex beat and S_3 are palpable. Cardiac enlargement or displacement of the heart by an intrathoracic mass may lead to an abnormal location of the cardiac impulse. A loud cardiac murmur often is associated with a palpable vibration or *thrill*.

TABLE 8-1 Auscultation of Cardiac Arrhythmias

RHYTHM	HEART RATE PER MINUTE	HEART SOUNDS	AUSCULTATION
SINUS MECHANISMS			
Sinus rhythm	Variable	S4–1–2 (3)[*]	Rate and rhythm depend on autonomic tone.
Sinus arrest/block	<26	S4–1-2 (3)	Irregular, long pauses.
Sinus bradycardia	<26	S4–1-2 (3)	Generally regular unless escape rhythm develops.
Sinus arrhythmia	25–50	S4–1-2 (3)	Irregular, cyclical change in heart rate; often interval varies between S_4 and S_1; often associated with second-degree atrioventricular block or sinus bradycardia.
Sinus tachycardia	>50	S4–1-2–3	Typically regular, but second-degree atrioventricular block may develop if sympathetic tone decreases.
SUSTAINED ATRIAL			
TACHYARRHYTHMIAS			
Atrial tachycardia and atrial flutter	>30	S1–2 (3)	Ventricular regularity and rate depend on atrioventricular conduction sequence, sympathetic tone; consistent S_4 absent; variable-intensity S_1; may detect independent atrial sounds.
Atrial fibrillation	>30	S1–2 (3)	Ventricular response irregular; rate related to sympathetic tone; heart rates consistently above 60 beats/min suggest significant underlying heart disease or heart failure; consistent S_4 is absent.
ECTOPIC RHYTHMS			

Junctional rhythm	26–200	S1–2 (3)	Heart rate usually regular idionodal rhythms or junctional tachycardia; heart rate depends on the mechanism and sympathetic tone; inconsistent S_4; variable intensity sounds.
Ventricular rhythm	26–200	S1–2 (3)	Heart rate may be regular during monomorphic, unifocal ectopic rhythm or irregular during polymorphic or multifocal ectopic activity; the heart rate depends on the mechanism (e.g., escape rhythm versus ventricular tachycardia); variable intensity and split heart sounds may be audible.
Premature atrial and junctional beats	Varies	Early S1-S2	Intensity of S_1 may be louder or softer than normal; the sounds are not usually split; less than compensatory pause follows the premature beat.
Premature ventricular beats	Varies	Early S1-S2	Intensity of S_1 often varies and ventricular beats may be softer than normal; heart sounds may be split from asynchronous ventricular activation heart sounds; compensatory pause typically follows a premature beat.
ATRIOVENTRICULAR BLOCKS			
Incomplete (first-and second-degree)	<50	S4–1-2 (3)	Heart rate varies; cyclic arrhythmia, variable S_4-S_1 interval; some variation in heart sounds.
Complete (third-degree)	<26	S4/S1–2 (3)	Ventricular escape rhythm, usually regular; independent atrial (S_4) sounds; variable-intensity heart sounds.

* Heart sounds in parentheses may be audible.

TABLE 8-2 Auscultation of Heart Sounds and Common Cardiac Murmurs

AUSCULTATORY FINDING	TIMING	POINT OF MAXIMAL INTENSITY (VALVE AREA)
NORMAL HEART SOUNDS		
First heart sound	Onset systole	Left apex and over the mitral valve
Second heart sound	End systole	Left base and over the aortic valve
Pulmonic component	End systole	Left base and over the pulmonic valve
Third heart sound	Early diastole	Left apex and over the mitral valve
Fourth (arterial) sound	Late diastole	Ventricular inlet (left)
FUNCTIONAL MURMURS[*]		
Systolic ejection murmur	Systole	Left base (aortic/pulmonic valves)
Early (proto-)diastolic	Diastole	Ventricular inlets (left/right)[†]
Late diastolic (presystolic)		Ventricular inlets (left/right)[†]
VALVULAR REGURGITATION[‡]		
Mitral regurgitation	Systole	Left apex and over the mitral valve[§]
Tricuspid regurgitation	Systole	Right hemithorax (tricuspid valve)
Aortic regurgitation	Diastole	Left base and over the aortic valve
Pulmonary insufficiency	Diastole	Left base and over the pulmonic valve
Ventricular septal defect[||]	Systole	Right sternal border/left cardiac base (pulmonic valve)
Patent ductus arteriosus	Continuous	Dorsal left base over the pulmonary artery

Modified from Bonagura JD: Clinical evaluation and management of heart disease, Equine Vet Educ 2:31–37, 1990.

Only typical features are considered: Apex refers to the ventral part of the heart, at the point of the palpable cardiac impulse (apex beat); base refers to the craniodorsal part of the heart over the outlet valves (aortic, pulmonic) where the second heart sound is most intense.

* The exact causes of functional (flow) murmurs have not been proved; however, systolic murmurs have been recorded within the aorta and pulmonary artery using intravascular phonocardiography. The systolic ejection murmur, which begins after the first heart sound and ends before the second heart sound, is the most commonly identified murmur; the protodiastolic murmur extends from the second to the third heart sound; the presystolic murmur is short and spans the fourth and first heart sounds. Functional murmurs may be musical.

†	Ventricular inlets refer to the parts of the thorax overlying the ventricular inflow tracts and include the areas just dorsal to the mitral and tricuspid valve areas and extend ventrally to the apical regions of the ventricles.
‡	Most cases of valvular regurgitation are evident throughout systole or diastole and extend into the second heart sound (holosystolic or pansystolic) or first heart sound (holodiastolic or pandiastolic); however, late systolic murmurs, which may be related to valve prolapse and minor chordal ruptures, have been identified with mitral or tricuspid valve insufficiency, and the murmur of aortic insufficiency may not always be holodiastolic. Documented reports of valve stenosis are rare. Murmurs of atrioventricular valve insufficiency are generally audible over the affected valve, project prominently toward the respective ventricular apex, and also radiate dorsally, following the regurgitant jet into the atrium. Occasionally, murmurs of tricuspid valve disease are prominent at the extreme left cranial heart border.
§	The murmur of mitral regurgitation often radiates well into the aortic valve area and dorsally into the left atrium.
‖	Murmurs caused by defects in the right ventricular inlet septum are most audible below the tricuspid valve and above the right sternal border and generate a softer systolic ejection murmur of relative pulmonic stenosis over the left cardiac base; murmurs from defects in the right ventricular outlet septum may be loudest over the pulmonary valve; flow across large nonrestrictive defects can be soft.

370

TABLE 8-3 Causes of Cardiac Murmurs

CARDIAC MURMUR	LESION IDENTIFIED BY ECHOCARDIOGRAPHY, CATHETERIZATION, OR NECROPSY
Functional murmurs*	No identifiable lesions
Congenital heart disease murmurs	Defect(s) in the atrial or ventricular septa; patent ductus arteriosus; atresia/stenosis of the tricuspid or pulmonic valve; valve stenosis; other malformations of the heart
Mitral regurgitation	High-level training; degenerative thickening of the valve; bacterial endocarditis; mitral valve prolapse into left atrium; rupture of a chorda tendinea; dilated-hypokinetic ventricle (dilated cardiomyopathy); papillary muscle lesion or dysfunction; valvulitis; malformation
Tricuspid regurgitation	High-level training†; same as mitral regurgitation; also pulmonary hypertension from severe left heart failure or chronic respiratory disease
Aortic regurgitation	Degenerative thickening of the valve; congenital fenestration of the valve; bacterial endocarditis‡; aortic prolapse into a ventricular septal defect or the left ventricle; flail aortic valve leaflet; valvulitis; malformation; ruptured aorta or aortic sinus of Valsalva
Pulmonary insufficiency	Bacterial endocarditis‡; pulmonary hypertension; flail pulmonic valve leaflet; valvulitis; malformation; rupture of the pulmonary artery
Murmur associated with vegetative endocarditis	Insufficiency of the affected valve‡

Modified from Bonagura JD: Clinical evaluation and management of heart disease, Equine Vet Educ 2:31–37, 1990.

* Functional murmur may be innocent (unknown cause) or physiologic (suspected physiologic cause). Functional murmurs are common in foals and trained athletes (athletic murmur); associated with fever and high sympathetic nervous system activity (pain, stress, sepsis); and often are heard in anemic horses. Functional murmurs depend on the physiologic state and can be altered by changing the heart rate. Such dynamic auscultation is useful in detecting functional murmurs.

† Doppler echocardiography can identify “silent” regurgitation across a right-sided cardiac valve in some horses; this is probably a normal finding of no clinical significance.

‡ Anatomic stenosis generally is caused by a large vegetation and also should be associated with a diastolic murmur of valvular insufficiency; increased flow across the valve, even in the absence of a true stenosis, may generate a murmur of “relative” valvular stenosis (e.g., with aortic regurgitation a systolic ejection murmur may occur because of an increased stroke volume).

8.3.3.2 Heart Sounds

Heart sounds should be easy to auscultate on both sides of the thorax, although some variability exists based on body type. Heart sounds are louder over the left thoracic wall. All four heart sounds generally are detectable in the standing horse, but all may not be audible at the same location (Figure 8-9).[4,23,25] The variable ventricular filling sound (S_3) is most localized and may be difficult to detect unless one places the bell lightly over the left apex. The intensity of the heart sounds should be consistent when the rhythm is regular; variation of heart sound intensity occurs with arrhythmias (irregular cardiac filling) and with volume-overloaded ventricles. Muffled heart sounds are audible with pericardial effusions or pericardial abscesses (in affected horses, the muffling may be only on one side of the thorax) but also occur in some horses with large pleural effusions and cranial mediastinal masses. Accentuation of all heart sounds, especially S_3, may be detectable with volume-loaded ventricles or with marked sympathetic activity.

S_1 varies after prolonged diastolic periods and often becomes louder (and sometimes softer). The intensity of S_1 varies whenever the rhythm is irregular, but this in itself is not diagnostic of an abnormality. Splitting of S_1, if pronounced, may indicate abnormal ventricular electric activation or ventricular premature complexes.[213] 371
Close splitting of S_1 may be more obvious with atrial fibrillation, and in the absence of an atrial sound, one 372
may misinterpret the split S_1 as a closely timed S_4-S_1 complex.

Figure 8-7 General areas for cardiac auscultation (left side). The typical flow murmur is loudest over the craniodorsal base *(upper oval)*. Murmurs of mitral regurgitation often project loudly to the left apex *(lower oval),* although dorsal radiation is also common. *Ao,* Aorta; *PA,* pulmonary artery; *AV*, aortic valve; *LV,* left ventricle; *RV,* right ventricle. (From Bonagura JD, Muir WW: The cardiovascular system. In Muir WW, Hubbell JAE, editors: *Equine anesthesia,* St Louis, 1991, Mosby.)

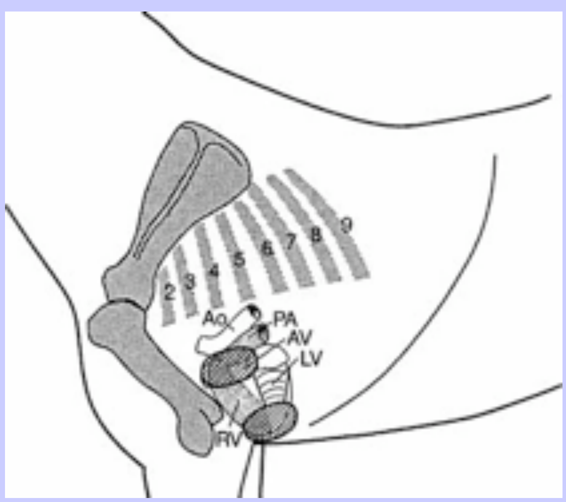

Figure 8-8 Cranial view of the heart demonstrating the U shape of the right ventricle *(RV)*. The tricuspid valve and the right ventricular inlet are located on the right side, whereas the outlet and pulmonary artery *(PA)* are on the left side. Murmurs of tricuspid regurgitation and perimembranous ventricular septal defects are typically loudest over the right hemithorax, whereas flow murmurs and those caused by subaortic or subpulmonic septal defects are loudest over the left cardiac base. *RA,* Right atrium. (From Bonagura JD, Muir WW: The cardiovascular system. In Muir WW, Hubbell JAE, editors: *Equine anesthesia,* St Louis, 1991 Mosby-Year Book.)

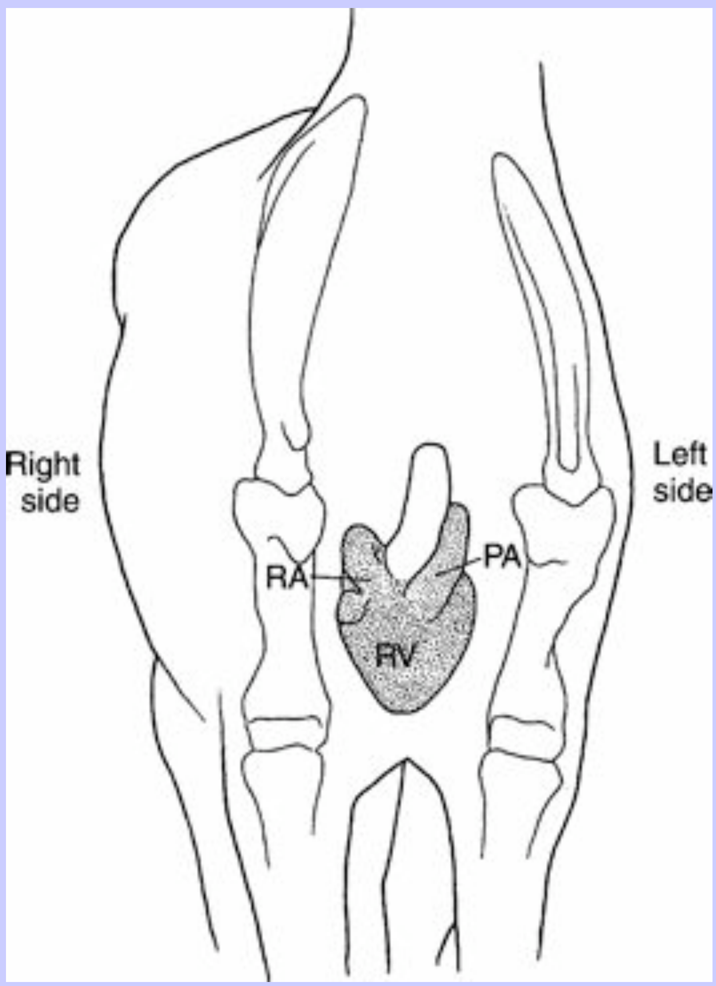


S_2 is loudest normally over the aortic valve area and may be split audibly over the pulmonic valve area.[3,4,213] This sound can be soft or absent following a premature beat and may be obscured by a holosystolic murmur. Audible splitting of S_2 occurs commonly in normal horses, varies with heart rate or respiration, and only infrequently is associated with pulmonary hypertension. The relative closure of the semilunar valves probably varies with the heart rate and pulmonary artery pressure,[4,213] although the pulmonic component most often is detectable after the aortic component in the healthy, resting horse. If the pulmonary component of S_2 develops a tympanic quality, becoming equal to or louder than the aortic component of S_2, the clinician should suspect pulmonary hypertension. Identification of a loud pulmonic S_2 is a useful clinical finding in cases of right-sided heart failure because it often indicates that a lesion on the *left* side of the heart has led to pulmonary hypertension and right-sided CHF.

Diastolic sounds are normal.[16,17,19,305] One should detect S_4 in virtually all horses, and this sound may be loud in some cases. One normally auscultates isolated atrial sounds at slow resting heart rates; however, multiple isolated S_4 sounds indicate high-grade atrioventricular block. S_3 is normal and can achieve great intensity with ventricular dilation and elevated filling pressures such as occur with heart failure.

One may detect other sounds with heart disease. Systolic clicks occur uncommonly over the great vessels and are thought to be benign. A systolic click that is most audible over the left apex may be a marker for mitral valve disease or prolapse of the valve into the left atrium. Constrictive pericardial disease may lead to a loud ventricular filling sound, a ventricular knock. In addition to muffling of sounds, pericarditis often is associated with a pericardial friction rub. The clinician classically detects these rubs during three portions of the cardiac cycle (systole, early diastole, late diastole). One must distinguish these sounds from pleural friction rubs or respiratory mediated sounds, which occasionally are associated with the cardiac cycle. Pleural and pulmonary rub tend to be heard only during one or two phases of the cardiac cycle and may not correlate closely.

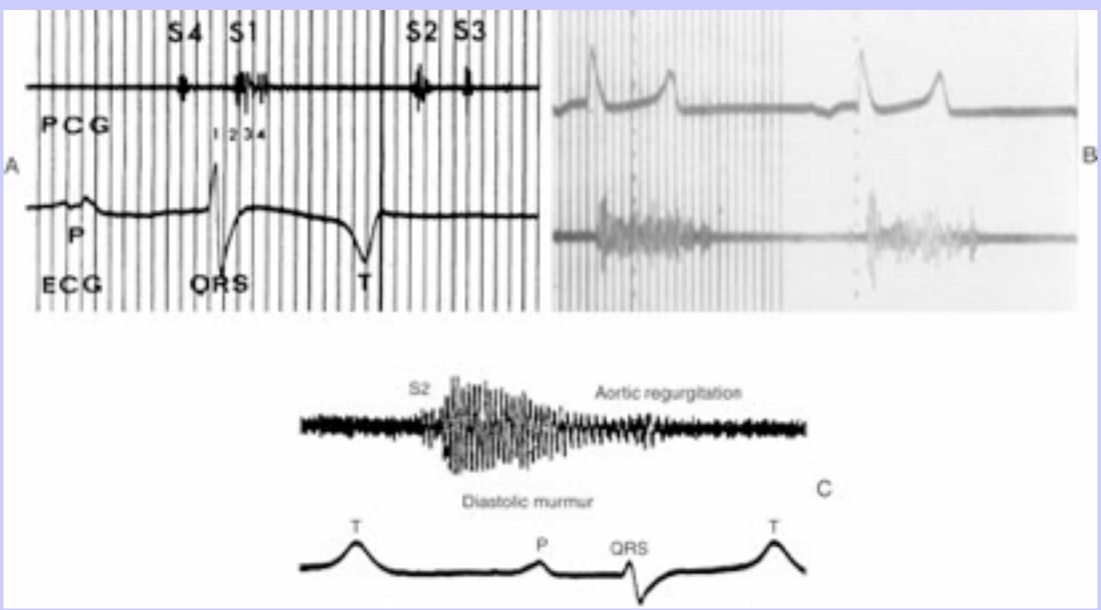
8.3.3.3 Heart Rate and Rhythm

Heart rate can change rapidly and dramatically, varying with autonomic efferent traffic and level of physical activity. Changes in the rate and rhythm are reflected in cardiac auscultation and palpation of the pulse (see Table 8-1).[299] The normal arterial pulse and cardiac rhythm is regular or cyclically irregular. Heart rate varies between 28 and 44 beats/min, although slightly slower heart rates are detectable in some fit racehorses and higher heart rates may be present in foals,[303] yearlings, Draft Horses,[309] and healthy but nervous horses. One commonly detects an elevated resting heart rate with late pregnancy, fever, pain, hypovolemia, severe anemia, infection, or shock. Persistent, otherwise unexplained tachycardia is also typical of heart failure wherein the standing heart rate usually exceeds 60 beats/min.

One must differentiate physiologic arrhythmias associated with high resting vagal tone from pathologic arrhythmias, because relaxed and fit horses have many normal bradyarrhythmias. The most common of these bradyarrhythmias is second-degree atrioventricular block (see Figure 8-3), which is reported in 15% to 18% of normal horses at rest and has been detected in up to 44% of normal horses with 24-hour continuous electrocardiographic monitoring.[172,175,177,310,311] Second-degree atrioventricular block is most common in fit 372
racehorses or in other high-performance animals and disappears with exercise or excitement or after 373
administration of atropine. Sinus arrhythmia also occurs regularly in horses and often is associated with sinus bradycardia and resting heart rates of 24 to 28 beats/min. Sinus arrhythmia may wax and wane with respiration; however, synchronization with ventilation is not a consistent finding in the horse and is more

likely related to changes in baroreceptor tone. Sinoatrial block and sinoatrial arrest occur sporadically in fit horses. Because these physiologic arrhythmias are associated with high vagal tone, the heart rate typically ranges from a low normal value to bradycardia. The clinician can undertake maneuvers that reduce vagal activity and increase sympathetic tone to ensure that the rhythm becomes normal. Successful methods include leading the horse through three or four tight circles, jogging, or lunging. One should recognize, however, that some horses redevelop physiologic atrioventricular block within 10 to 60 seconds following completion of such maneuvers. If the arrhythmia persists after exercise, or if the auscultatory findings suggest another arrhythmia (see Table 8-1), the clinician should obtain an ECG.

Figure 8-9 Phonocardiograms *(PCG)*. **A,** The four normal heart sounds (S1 through S4) are evident in this recording. (The numbers *1* through *4* indicate the various components of the first heart sound; *ECG,* electrocardiogram.) **B,** Systolic murmur recorded from a yearling with a ventricular septal defect. (P waves on the electrocardiogram are negative in this tracing.) **C,** Decrescendo, musical, holodiastolic murmur recorded from a horse with aortic regurgitation. The murmur begins in early diastole (after the T wave) and ends at the QRS complex. (A recording courtesy of D. Smetzer, R.L. Hamlin, and C.R. Smith.)



The arrhythmias associated with heart disease occur most often with normal to increased heart rates, with the exception of advanced second-degree and complete (third-degree) atrioventricular block (see Table 8-1).[*] Atrial premature beats are characterized by a regular cardiac rhythm, which is interrupted suddenly by an earlier than normal beat(s). Because the sinus node resets during an atrial premature beat, the following pause is usually incomplete or less than compensatory. The atrioventricular node also can block premature atrial

beats, leading to a sudden pause in the rhythm. A ventricular premature beat is followed by a fully compensatory pause unless the extrasystole is interpolated between two normal sinus beats. Pulse deficits (more first sounds than arterial pulses) are expected with premature beats.

Atrial fibrillation is characterized by an irregular rhythm, with beats occurring sooner than expected, and pauses in the rhythm with no consistent underlying diastolic interval. The atrial contraction and hence S_4 are 373

absent in atrial fibrillation. Infrequently, atrial fibrillation develops with recurring periodicity of cycle lengths that can cause difficulty in distinguishing this abnormal rhythm from second-degree atrioventricular block. [169,171,179] Another diagnostic pitfall can be the presence of a split S_1, because the clinician may mistake this for a closely timed S_4-S_1 complex. 374

Atrial tachycardia, however, may develop regular atrioventricular conduction and rapid regular rhythm. At rest, however, horses with atrial tachycardia generally have irregular rhythms because of frequent second-degree atrioventricular block but with heart rates that are slightly higher than normal. Auscultation of the horse in a quiet area may reveal isolated audible S_4 sounds associated with the second-degree atrioventricular block. Junctional and ventricular tachycardias usually are manifested by a rapid regular rhythm, unless the arrhythmia is multiform, in which case the heart may sound irregular, such as in atrial fibrillation. Because of associated atrioventricular dissociation or abnormal ventricular activation, the heart sounds may be split or variable in intensity.

* References 2, 3, 33, 103, 299, 312–314.

8.3.3.4 Cardiac Murmurs

Cardiac murmurs are prolonged audible vibrations developing in a usually quiet portion of the cardiac cycle. In general, murmurs are manifestations of normal (functional) or abnormal (pathologic) blood flow in the heart and blood vessels. Although many heart murmurs are functional (physiologic and innocent), other murmurs provide evidence of heart disease and may require further investigation. Most *functional* cardiac murmurs are caused by vibrations that attend the *ejection* of blood from the heart during systole or the *rapid filling* of the ventricles during early diastole.[*] Causes of abnormal murmurs include incompetent cardiac valves, septal defects, vascular lesions, and (rarely) valvular stenosis (see Tables 8-2 and 8-3). The continuous murmur of patent ductus arteriosus is considered a normal finding in full-term foals for up to 3 days after parturition but occasionally persists for almost a week after foaling.[233,298,303,318]

One of the challenges of physical diagnosis is determination of the cause and clinical significance of a cardiac murmur. With knowledge and experience the clinician can determine accurately the *likelihood* that a murmur is physiologic or pathologic and can select animals requiring additional studies efficiently. The clinician should describe the *timing, duration, quality or pitch, grade, point of maximal murmur intensity,* and *radiation* of a murmur (see Table 8-2), as well as the effect of changing heart rate on the sounds. One determines the timing relative to the heart sounds and designates murmurs as systolic, diastolic, or continuous. When the overall timing is not obvious, the clinician can palpate the apical impulse, which occurs in early systole, or the systolic pulse in the brachial or median artery to identify the timing of the murmur. Skilled auscultators subdivide the timing of murmurs into proto-, meso-, or telesystole or proto-, meso-, and telediastole (early, middle, or late, respectively) because the timing and duration of the murmur often correlate with specific flow disturbances. Shorter murmurs, especially those occurring in early systole or protodiastole, are more likely to be functional, although this is not always the case. Experience also teaches that loud murmurs are more likely to be associated with cardiac pathology, but again exceptions occur. The pitch or quality of the murmur

provides additional insight. For example, mixed frequency (harsh or blowing) murmurs are typical of cardiac disease. A brief vibratory or musical murmur is typically functional; however, a prolonged musical murmur suggests a valvular lesion. Applying the characteristics of murmurs to the clinical setting requires study, an organized scheme, and practice. When one believes a murmur to represent an underlying cardiac pathologic condition, further investigation is necessary. The overall significance of the hemodynamic abnormality should include consideration of the work history, general physical examination, presence or absence of heart enlargement or cardiac failure, and results of ancillary tests such as echocardiography, electrocardiography, and exercise performance (or testing).

Functional, innocent, or physiologic heart murmurs are common and are not attributed to pathologic conditions of the heart. Such murmurs may be related to the large size and tremendous inflow and outflow volumes of the equine heart.[315] Physiologic causes of functional murmurs include fever, high sympathetic activity (e.g., colic, exercise, and pain), moderate to severe anemia, and peripheral vasodilation. These murmurs are typically soft (grades 1 to 3 out of 6), localized, and short; they crescendo-decrescendo in time; and they are labile. Increasing heart rate usually increases the intensity and duration of a functional murmur, although in some horses the murmur becomes less intense. Functional murmurs are not holosystolic or holodiastolic; therefore the heart sounds should still be evident.

The most common functional murmur is the systolic ejection murmur heard over the aortic and pulmonic valves and into their respective arteries at the left cardiac base (see Figure 8-7).[4] The functional ejection murmur is generated by flow into the great vessels and by definition must start after S_1 and end before S_2. Nonetheless, in some horses the functional ejection murmur can achieve substantial intensity (rarely, a grade 4 or 5 out of 6), and may seem holosystolic at higher heart rates. At times a remarkable change in functional 374
murmur intensity occurs from one day to another; for example, the varying murmurs identified in some horses 375
with emergent colic. Because a loud functional murmur can radiate caudally, one may confuse the murmur with MR. In terms of diagnostic considerations, the clinician should not mistake a functional ejection murmur for that of aortic or pulmonic stenosis. Pulmonic stenosis is rare in the horse; aortic stenosis is rarer. Accordingly, one rarely entertains these valvular malformations in the differential diagnosis. The subpulmonic (subarterial) VSD may be loudest over the great vessels, but such murmurs are typically loud and usually prompt echocardiographic investigation.

Functional diastolic murmurs are also common, especially in young horses and in the Thoroughbred breed. These murmurs are generally soft and detectable over the LV or RV inlets, from the dorsal atrium to the ventricular apex. The functional protodiastolic murmur is an early diastolic murmur detected between S_2 and S_3. The murmur may be musical, vibratory, or squeaky and typically accentuates with increased heart rate.[4] The murmur most reasonably represents the rapid early filling of the ventricles. The presystolic functional murmur is audible between S_4 and S_1, may sound like a rub or long heart sound following the atrial contraction, and can be confused with an early systolic murmur or a friction rub.

The most commonly detected murmurs associated with structural heart disease are those generated by TR, MR, aortic regurgitation, and VSD. Tables 8-2 and 8-3 indicate typical causes and auscultatory features of these murmurs, which are described in detail later in this chapter. Detection of a cardiac murmur indicative of valvular disease or a congenital cardiac defect necessitates additional studies to assess the situation objectively. Certainly, the clinician should consider the history, because the horse with excellent performance and good exercise tolerance is unlikely to have serious heart disease. Auscultation, however, is insufficient to distinguish trivial from significant heart disease in the poorly performing horse or in a horse with a cardiac arrhythmia. Echocardiography is helpful in these cases to quantify heart size and objectively assess ventricular

function. One can identify or discount underlying lesions such as a valve vegetation, ruptured valve chorda tendinea, or dilated cardiomyopathy. Doppler echocardiography can document abnormal blood flow and can pinpoint the cause of a murmur. One cannot obtain this type of objective information as easily or as effectively by other noninvasive methods. Other methods of assessing the significance of heart murmurs are thoracic radiography, exercise testing, radionuclide angiography, and cardiac catheterization. Cardiac catheterization has been largely replaced by Doppler echocardiography.

Figure 8-10 Peracute pulmonary edema in a horse with a ruptured chorda tendinea. The photo was taken immediately after euthanasia. An important note is that tracheal froth is often a postmortem artifact, particularly when observed hours after death.

8.3.3.5

Pulmonary Auscultation

Auscultation of the lungs should reveal normal breath sounds with the horse at rest, while ventilating into a rebreathing bag, and after exercise. Decreased or absent airway sounds or large airway sounds in the ventral portions of the thorax indicate a pleural effusion, a common finding in biventricular or right-sided heart failure. Moist or bubbling (fluid) sounds or crackles (i.e., rales) are not auscultated commonly in the lungs of horses with pulmonary edema and left-sided heart failure. Instead, tachypnea associated with harsh bronchovesicular breath sounds is usually audible, because horses with chronic left-sided CHF seem to develop more interstitial than alveolar pulmonary edema. When alveolar edema does develop, respiratory distress may be severe, and free fluid may be auscultated in the trachea. On rare occasions, primarily with peracute left-sided heart failure, froth is visible at the nares and the horse will cough and expel large quantities

of pulmonary fluid (Figure 8-10). Such horses demonstrate severe respiratory distress (marked tachypnea and dyspnea), anxiety, and agitation.

8.3.4 EXAMINATION OF THE PERIPHERAL VASCULATURE

An evaluation of the peripheral vasculature is part of a cardiovascular workup and should include examination of the arteries and veins in the head, forelimbs, and hindlimbs. When possible, one also should measure arterial blood pressure. The genesis of the arterial and venous pulse has been described previously. The heart sounds should correlate with the jugular and arterial pulses. One can identify heart rate and rhythm, as well as altered 375
hemodynamic states, by palpating the facial artery pulse, which can be described as normal, hypokinetic (weak), 376
hyperkinetic, or variable. Irregularity often indicates a cardiac arrhythmia. Abnormalities of arterial pressure and perfusion may cause changes in mucous membrane color and capillary refill time. Refill time is prolonged with hypotension or peripheral vasoconstriction; conversely, it may be shortened with vasodilation.

Normal quality *arterial pulses* should be palpable in the facial, median, carotid, great metatarsal, coccygeal, and digital arteries. Thready or hypokinetic arterial pulses are detectable in CHF and in diseases associated with cardiovascular collapse, such as endotoxemia, or after profuse hemorrhage. Thready arterial pulses also may be detectable only in the hindlimbs with aortic-iliac thrombosis. Bounding, hyperkinetic arterial pulses are palpable with clinically significant aortic regurgitation, patent ductus arteriosus, and aortic to pulmonary or aortic to right-sided heart fistulae. Great variation in the intensity of the pulse usually occurs with arrhythmias, particularly atrial fibrillation and multiform ventricular tachycardia. A pulse deficit (S_1 without palpable pulse) occurs when developed LV pressure does not exceed aortic pressure. Deficits are likely to be palpable in association with arrhythmias, particularly premature beats or following short diastolic periods of tachyarrhythmias.

Palpation of the arterial pulse is a crude indication of the *arterial blood pressure,* representing the difference between peak systolic and diastolic pressures, the rate of rise of arterial pressure, and the physical characteristics of the artery and surrounding tissues. One can measure arterial blood pressure directly by arterial puncture or cannulation or indirectly using various auscultatory, Doppler, or oscillometric techniques.[68,221,237,319–344] With percutaneous placement of an arterial catheter in the facial or transverse tibial artery, frequently one can monitor pressure invasively in critically ill or anesthetized horses. Indirect methods have been used successfully to monitor pressure in the coccygeal artery; however, these methods are less sensitive in hypotensive animals and may lag in response during rapid changes in blood pressure.[322,324,326] One must direct attention to placement and diameter of the occluding cuff when using indirect methods,[336] and the optimal width of the cuff (bladder) is between approximately one quarter to one fifth of the circumference of the tail when measuring pressure in the middle coccygeal artery.[330,335] The arterial pulse wave itself varies, depending on the site of measurement, and the distal arterial systolic pressure may be higher and the diastolic pressure lower than the corresponding aortic pressures.

Arterial blood pressure monitoring includes determination of systolic, diastolic, and mean pressures. Arterial pressure is determined by the interplay between stroke volume, heart rate, and vascular resistance (see Box 8-3; Figure 8-3). Significant increases in CO, during exercise for example, lead to significant increases in arterial blood pressure with systolic pressures exceeding 200 mm Hg.[214,341,345]

Normal reported values for indirect arterial pressure are 111.8 mm Hg systolic (ranging from 79 to 145 mm Hg) and 67.7 diastolic (ranging from 49 to 106 mm Hg).[*] The values obtained at the coccygeal artery are slightly lower than central arterial pressures, but this is not a problem when monitoring an individual horse. Blood pressure is lowest in neonates and rises during the first month of life to the normal adult range.[221,324] Some

variation exists among breeds. Draft breeds tend to have lower pressures than do racehorses, and Standardbreds have lower pressures than do Thoroughbreds.[340] Arterial pressures fluctuate slightly with ventilation and significantly with positive pressure ventilation or cyclic changes in heart rate. Posture imposes a significant influence on arterial pressure, because raising the head from the feeding position necessitates a higher aortic pressure to maintain cerebral perfusion pressure. Obviously, lowering of the head minimizes the hydrostatic pressure imposed during raising of the head. Mean arterial pressure measured in the middle coccygeal artery can vary approximately 20 mm Hg with the changing head position.[337]

The left ventricle generates the systolic arterial pressure, which consequently is affected by the interplay between the stroke volume, aortic compliance, and previous diastolic blood pressure. Arterial *pulse pressure,* the difference between systolic and diastolic values, depends greatly on stroke volume and the peripheral arteriolar resistance that determines the runoff of diastolic pressure. Pulse pressure determines the intensity of the palpable peripheral arterial pulse. Ventricular failure reduces pulse pressure, whereas abnormal diastolic runoff (aortic insufficiency, generalized vasodilation) widens the pulse pressure. Diastolic and mean pressures are better estimates of perfusion pressure; arteriolar vasoconstriction or higher CO increases these variables.

One should examine the cutaneous veins for distensibility, refill, thrombosis, and estimated venous pressure. *Jugular pulsations* are normally observable in the thoracic inlet and up to the ventral one third (10 cm) of the neck. These pulsations reflect right atrial pressure changes (discussed previously) and are visible along the entire length of the jugular vein when the head is lowered below the level of the heart. The carotid arterial pulse may be transmitted through the jugular furrow and mimic an abnormal systolic pulse wave in the jugular vein if the vein 376
is distended. Occluding the jugular vein ventrally can demonstrate if the pulses are actually originating in the 377
right atrium, because light digital pressure over the vein prevents venous pulse transmission, or prominent collapse. One may observe pronounced jugular pulsations occasionally in excited but otherwise normal horses with high sympathetic tone. In some of these cases the venous collapse is the most prominent movement and the pulse is simply normal venous filling. When in doubt, one can verify this finding by simple ultrasound imaging of the ventral portion of the vein. The jugular veins in normal horses are collapsed, but the veins in the limbs and on the torso are visible and somewhat filled. Venous pressure in the jugular vein is normally less than 10 cm of water above the phlebostatic point.

Figure 8-11 Jugular venous distention in a Shire foal with biventricular congestive heart failure caused by congenital heart disease.

One can observe abnormal jugular pulses with arrhythmias causing atrioventricular dissociation, with diseases of the tricuspid valve, and with RV failure. An abnormal jugular pulse is one that extends proximally up the jugular vein for more than 10 cm in systole (with the head of the horse held in a normal position) or that demonstrates retrograde filling from the heart when one occludes the vein dorsally. Doppler studies of the jugular vein can distinguish a prominent pulse caused by retrograde flow from an apparent pulse caused by prominent collapse and normal filling. Generalized venous distention, often accompanied by subcutaneous edema, is characteristic of heart failure (Figure 8-11). Distention of only the veins cranial to the thoracic inlet should indicate a cranial mediastinal mass or abscess with obstruction of the cranial vena cava and not CHF.[94] Prolonged refill of the saphenous vein indicates the possibility of aortic-iliac thrombosis and decreased arterial supply to the affected limb.[197–202,347,348] Distended veins that are firm on palpation, with considerable distention of the more proximal veins, indicate probable venous thrombus.[349]

Figure 8-12 Ascites, ventral edema, and weight loss are evident in this mare with right-sided congestive heart failure. The distended lateral thoracic vein *(arrow)* is evident caudal to the triceps.

8.3.5

CONGESTIVE HEART FAILURE

CHF in horses is uncommon; however, one generally can make a diagnosis of this pathophysiologic state during a complete physical examination.[350] Important clinical findings include persistent tachycardia (typically heart

rate higher than 60 beats/min), jugular distention and pulsation, abnormal arterial pulses, fluid retention (ventral subcutaneous edema, pleural effusion, or pulmonary edema), and loss of body condition (Figure 8-12). LV failure following valvular or myocardial heart disease causes pulmonary venous congestion with pulmonary interstitial or, uncommonly, alveolar edema. Tachypnea or coughing associated with lung edema of left-sided CHF frequently is misdiagnosed as pneumonia or chronic obstructive pulmonary disease. One also may detect lethargy, exercise intolerance, collapse (or syncope), anorexia, depression, and weight loss with CHF or cardiac insufficiency. Heart failure is discussed more fully later in this chapter.

8.4 Diagnostic And Laboratory Studies

8.4.1 EXERCISE TESTING

Exercise testing is an increasingly important part of the complete cardiovascular evaluation.[95,288] Although the sensitivity, specificity, and specific endpoints of the exercise test (as it pertains to detection of organic heart disease) are not defined completely, exercise studies may detect subtle cardiovascular disease or unmask a serious problem such as a ventricular tachyarrhythmia. Because most horses function as athletes, one should include some form of exercise testing in the prepurchase cardiovascular examination, unless the animal is too young to perform or is to be used solely for breeding. Even in these situations, evaluation of a foal, weanling, or yearling after a period of free exercise is optimal. Furthermore, one should determine that a stallion has sufficient stamina to perform in the breeding shed. Thus the clinician should evaluate the cardiovascular system at rest and immediately after exercise and under the anticipated form of work required by the prospective owner. Increasingly, standardized treadmill testing is used to detect subtle clinical abnormalities that limit peak performance.[183,283–287,351,352] Treadmill exercise is also important when evaluating the horse with a history of collapse or syncope, because one should evaluate the cardiac response to exercise without risk to a rider.

377
378

Changes in heart rate with exercise have been well studied.[183,283–287,351,352] The normal horse develops sinus tachycardia, shortening of conduction intervals, and significant ST-T alterations associated with exercise. The maximal heart rate achieved depends on the level of exercise performed. At heart rates of less than 100 to 120 beats/min, sinoatrial node discharge is labile and subject to psychologic influences. Once the horse commences exercise, the heart rate should accelerate and then stabilize at a level appropriate for the work being performed. As a general guideline, heart rates of 70 to 120 beats/min are normal at the trot, 120 to 150 beats/min at the canter, 150 to 180 beats/min at a hard gallop, and more than 180 beats/min when galloping. The maximal heart rate for most horses is between 210 and 240 beats/min, although some animals develop higher rates. A linear relationship exists between heart rate and the velocity or work effort of exercise when the heart rate is between 120 and 210 beats/min. Heart rate usually recovers rapidly and falls to less than 100 beats/min within 5 minutes of cessation of exercise. Many factors influence the recovery of heart rate to the resting level, including the humidity, ambient temperature, training, fitness, work performed, psychologic factors, and state of cardiovascular health. After maximal work, such as a race, an hour may pass before the heart rate completely recovers to the resting rate. An inappropriately high heart rate for a given level of exercise may simply denote a healthy but unfit horse; however, this finding also can indicate the presence of cardiovascular, pulmonary, or musculoskeletal disease. Information about the heart rate is particularly useful when a horse has the heart rate monitored routinely during exercise.

One may observe exercise-induced arrhythmias during or after exercise. During the recovery period following exercise, horses have large fluctuations in sympathetic and parasympathetic tone. Arrhythmias are common during this time, even if the heart rhythm was normal at rest and at peak exercise. One most frequently detects significant sinus arrhythmias, second-degree atrioventricular block, supraventricular ectopia, and ventricular

premature beats in the immediate postexercise period. When one detects arrhythmias during a routine postexercise examination, an exercising ECG obtained by radiotelemetry is necessary to determine if the arrhythmia is present during exercise. One may use a heart rate monitor to provide an indication of arrhythmias during exercise; however, the detection of erratic heart blips or beeps does not adequately characterize the arrhythmia. With the exception of vagally mediated arrhythmias, one should consider postexercise arrhythmias suspicious. One should consider frequent or repetitive supraventricular or ventricular premature beats detected after exercise to be abnormal.

Arrhythmias that may be induced during exercise include supraventricular premature complexes, atrial fibrillation, and ventricular extrasystoles. One should include exercise-induced (paroxysmal) atrial fibrillation in the differential diagnosis of horses with poor performance during high-intensity exercise.[39,353,354] Recognition of this arrhythmia may require ambulatory electrocardiography or radiotelemetry ECG recordings during an exercise test. Exercise-induced ventricular arrhythmias are a concern because ventricular rhythm disturbances can lead to poor performance, sudden stopping, or even falling, and have been suspected as one cause of sudden death.[59,61–64] Repetitive ventricular activity (paroxysmal ventricular tachycardia) is particularly worrisome and may indicate preexisting myocardial disease or myocardial ischemia with altered cardiac electric activity. Some horses require a maximal performance to elicit abnormal cardiac rhythms. Performance problems detected only at the peak of exercise necessitate performing a treadmill exercise test to exhaustion in an attempt to investigate whether cardiac arrhythmias are a cause of the poor performance. This is particularly important if one suspects cardiovascular disease from the history or clinical examination.

One may use exercise echocardiography in an attempt to identify myocardial dysfunction.[288,355,356] When examined within 2 to 3 minutes following high-intensity exercise and with the heart rate exceeding 100 beats/min, the normal horse demonstrates a symmetric increase in LV shortening with increase in shortening fraction and cross-sectional shortening area. One can view these changes from the short-axis tomograms and prominent thickening of the septum and LV free wall from long-axis images. Persistent abnormalities in regional myocardial contraction suggest vascular disease with ischemia, preexistent myocardial fibrosis, or localized conduction disturbance. Myocardial isoenzymes may be elevated in some cases.[288] 378

379

8.4.2 ELECTROCARDIOGRAPHY

8.4.2.1 Normal Cardiac Cell Electric Activity

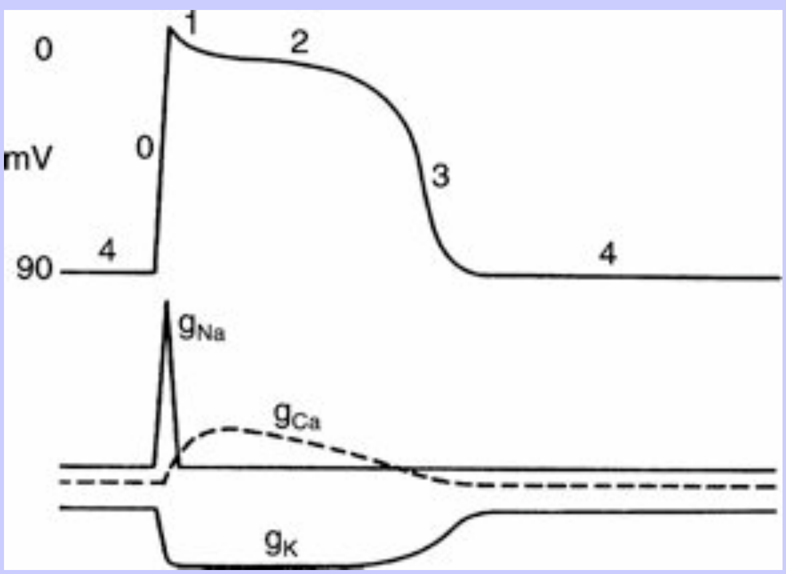
Myocytes in the atria and ventricles are excitable, and some of the specialized cardiac tissues are capable of spontaneous depolarization independent of extrinsic innervation. The processes responsible for generation of electric activity in the heart are caused by ion fluxes across the cell membrane.[70,181] The ECG represents this electric activity. The clinician requires a general understanding of cellular activity, generation, and spread of the cardiac electric impulse; effects of autonomic innervation; and electrocardiographic lead systems to interpret the equine ECG.

The partially selective nature of the cardiac cell membrane and the presence of various cell membrane pumps lead to a situation in which ions are partitioned unequally across the cell membrane.[70] This partitioning results in high potassium and low sodium concentrations intracellularly compared with the extracellular fluid. Other ions including chloride and magnesium, but most notably calcium, are important to cellular electric activity. Calcium also is essential for cardiac contraction. Sudden changes in cardiac cell membrane permeability or conductance to sodium, calcium, potassium, and chloride are responsible for the processes of depolarization,

muscular contraction, and repolarization. In turn, serum electrolyte concentration, acid-base status, autonomic traffic, myocardial perfusion and oxygenation, heart disease, and drugs affect these processes. The basic cellular processes of depolarization, calcium influx, and repolarization form the basis for, respectively, the P and QRS complexes of the ECG, myocardial contraction, and the ST-T wave of the ECG.

The resting membrane potential is determined primarily by the partitioning of potassium ions and proteins across the cell membrane and the relative impermeability of the membrane to sodium. *Depolarization* of atrial and ventricular myocytes and Purkinje fibers is caused by a fast current related to a rapid influx of extracellular sodium into the cell.[72,181,311] Phase 0 of the cardiac cell action potential recording represents depolarization (Figure 8-13). Cardiac tissues depolarized in this manner normally conduct electric impulses at high velocity. In contrast, the cells of the sinoatrial and atrioventricular nodes, as well as ischemic cells, demonstrate less negative diastolic membrane potentials. These cells depend on a slow inward current of depolarization carried mainly by calcium ions. Because of this property, cells in the sinoatrial node, atrioventricular node, and ischemic tissue conduct electric impulses slowly and can be involved in blocks, abnormal automatic mechanisms, or reentrant pathways that promote cardiac arrhythmias. Antiarrhythmic drugs act differently on tissues that are fast versus slow current dependent (see the section Cardiac Arrhythmias).

Figure 8-13 The cardiac action potential. The diagram demonstrates the phases of depolarization and repolarization as well as membrane conductance *(g)* to important ions (see the text for details). (From Berne RM, Levy MN: *Cardiovascular physiology,* St Louis, 1986, CV Mosby.)



The influx of extracellular calcium into the cell during phase 2 of the action potential triggers the release of intracellular calcium from the sarcoplasmic reticulum. Increases in cytosolic calcium cause myocardial contraction. Hypoxia, acidosis, and many drugs can affect myocardial contractility by interfering with calcium entry into cells, with the release of calcium from the sarcoplasmic reticulum, or with the binding of calcium to

contractile filaments.[70,97,181] Conversely, digitalis glycosides, dobutamine, and dopamine increase calcium influx and myocardial contractility.

Cellular *repolarization* is initiated by a decrease in the cell membrane conductance to sodium and calcium coincident with increased conductance to potassium. As intracellular potassium moves out of the cell, along its concentration gradient, phase 3 of the cardiac action potential occurs. Sympathetic stimulation also may activate an inward chloride current that facilitates repolarization at higher heart rates. Hypoxia and abnormalities in serum potassium or calcium alter this process. Hyperkalemia accelerates repolarization and shortens the ST-T wave of the ECG. This shortening occurs because hyperkalemia *increases* membrane permeability to potassium and the high intracellular potassium (exceeding 100 mmol/L) is more than adequate to drive potassium out of the cell (because extracellular potassium rarely exceeds 10 mmol/L).

Spontaneous depolarization or automaticity is a property of select cardiac tissues. Such activity is most prominent in the sinoatrial node but also may occur in cells around the atrioventricular node and in cells of the His-Purkinje network. Normal automaticity is observable during phase 4 of the cardiac action potential. 379
Spontaneous *pacemaker activity* is generated in normal pacemaker tissues by the background inward sodium 380
current and a time-related decrease in membrane permeability to potassium ion efflux.[181] Once membrane threshold is reached, short- and long-lasting calcium channels open, allowing the cell to depolarize via a slow inward current. The spontaneous depolarization process is modified greatly by vagal and sympathetic efferent traffic. With sympathetic stimulation and at higher heart rates additional inward currents, such as funny current, become activated. Depression of normal sinoatrial automaticity or increased activity in other tissues in the atria, Purkinje system, or in cells around the atrioventricular node may lead to an abnormal or ectopic cardiac rhythm. When the principal abnormality resides in depression of sinoatrial node function or blockage of the impulse in the atrioventricular node, the slow discharge of a subsidiary pacemaker is termed an escape mechanism. The normal purpose of these latent cardiac pacemakers is to rescue the heart from extreme bradycardia or asystole. However, ectopic pacemakers often are enhanced by drugs, inflammation, sympathetic activity, electrolyte disturbances, or ischemia, leading to *ectopic* rhythms that manifest as premature complexes or tachycardias. Other electrophysiologic mechanisms, including reentry and myocardial fibrillation, account for the development of other arrhythmias.

8.4.2.2 Genesis of the Electrocardiogram

The sinoatrial node is located near the right auricle; therefore initial cardiac muscle depolarization crosses the right atrium (see Figure 8-3). Activation waves spread through the atrial myocardial cells to the left atrium and also in the direction of the atrioventricular node. Specialized atrial muscle cells composed of internodal pathways and Bachman's bundle facilitate transmission of current across the atria.[8,357] These specialized pathways, as well as the sinoatrial node, differ functionally from normal atrial muscle, are resistant to high serum potassium concentrations, and still are activated during hyperkalemia.

Conduction continues across the atrioventricular tissues by first entering the atrioventricular node. Current transmission across the atrioventricular nodal cells is particularly slow because depolarization depends on slow current and is subject to physiologic blockade caused by varying vagal efferent activity.[170] Conduction proceeds at a greater velocity through the bundle of His and bundle branches. Propagation of the impulse through the ventricles is enhanced by a rapidly conducting Purkinje system that penetrates completely through the ventricular myocardium.[6,7]

Autonomic traffic affects these processes dramatically. Parasympathetic activity depresses sinoatrial nodal activity, enhances intraatrial conduction by shortening atrial action potential duration, and slows atrioventricular nodal conduction. Conversely, sympathetic efferent traffic increases heart rate and shortens atrioventricular conduction time.[181] Sympathetic activity also increases cellular excitability, predisposes to some cardiac arrhythmias, and increases myocardial oxygen consumption by augmenting the heart rate, force of myocardial contraction, and myocardial wall tension. Parasympathetic efferent traffic dominates in the resting, standing horse and frequently fluctuates with changes in blood pressure (see Figure 8-3). The pronounced sinus arrhythmia, sinoatrial block, and second-degree atrioventricular block so often encountered in the normal horse is caused by changing vagal tone and serves to regulate arterial blood pressure at rest.[68]

Figure 8-14 A normal equine base-apex lead electrocardiogram (25 mm/sec; 1 cm equals 1 mV). The waveforms are indicated. The QRS complex often lacks an R wave in this lead (QS complex). The T wave is labile and may be negative, biphasic, or positive. Increases in heart rate or sympathetic tone usually lead to positive T waves in this lead.

The ECG graphs the time-voltage activity of the heart. The average electric potential generated by the heart muscle is recorded throughout the different phases of the cardiac cycle with time displayed along the x-axis and electric potential inscribed vertically (Figure 8-14). The normal waveforms are the P wave (atrial depolarization), P-R interval (mainly caused by atrioventricular nodal conduction), QRS complex (ventricular depolarization), and ST-T wave (ventricular repolarization). A prominent atrial repolarization wave (Ta wave) often is noted in the P-R segment of the equine ECG, particularly at faster heart rates. The QT interval represents total electric activation-repolarization time.

8.4.2.3 Clinical Electrocardiography

The clinical application of electrocardiography to the horse has been studied extensively.[*] The principles of recording and interpreting the equine ECG are similar to those used for human beings, dogs, and other species.[103,363] The lead systems used are identical, although some modified leads, such as the base to apex lead, have 380
been found to be useful in monitoring the cardiac rhythm of the horse. A number of semiorthogonal lead 381
systems have been evaluated experimentally but rarely are used in clinical practice. The modified Einthoven's lead system consisting of leads frontal planes I, II, III, aV_R, aV_L, and aV_F and lead V_{10} is applicable for ECG studies of horses (Box 8-7). The base-apex lead or chest leads most often are used for rhythm analysis.

The value of continuous, ambulatory (Holter) ECG monitoring is obvious for identification of infrequent rhythm disturbances, quantifying the severity of an arrhythmia, or objectively evaluating drug therapy (Figure 8-15). In one study, many horses that were historically and clinically without evidence of cardiac disease were observed to have supraventricular or (less often) ventricular arrhythmias.[310] The clinician can perform Holter monitoring with contact electrodes using a bipolar lead system similar to that used for the equine heart rate monitors. One usually places electrodes over the left saddle area and sternum and keeps them moist and in contact with the horse using a surcingle and padding material. This type of continuous 24-hour rhythm monitor can be useful to evaluate the horse with a history of syncope or an arrhythmia but in which one cannot induce an arrhythmia during resting, exercise, and postexercise ECG examinations.

8.4.2.3.1

BOX 8-7 ELECTROCARDIOGRAPHIC LEADS

8.4.2.3.1.1

Frontal Plane Leads

Bipolar leads

- Lead I = Left foreleg [+] – right foreleg [–]
- Lead II = Left hindleg [+] – right foreleg [–]
- Lead III = Left hindleg [+] – left foreleg [–]

Unipolar augmented limb leads

- Lead aV_R = Right foreleg [+] – left foreleg and left hindleg [–]
- Lead aV_L = Left foreleg [+] – right foreleg and left hindleg [–]
- Lead aV_F = Left hindleg [+] – right foreleg and left hindleg [–]

8.4.2.3.1.2

Precordial Leads

Base-apex monitor lead

- Positive electrode over the left apex compared with the negative electrode over the right jugular furrow[*]

Precordial V leads[†]

- Positive electrode over the selected precordial site; the lead is named based on the location of the exploring (V or C) electrode

Lead V_3: near the left apex

Lead V_{10}: over the dorsal spinous processes (interscapular)

* The most common method of obtaining the base-apex lead is to place the left foreleg electrode over the left apex, the right foreleg electrode over the jugular furrow (or at the top of the right scapular spine), and select lead I on the electrocardiograph. This lead is an excellent choice to monitor the cardiac rhythm.

† Precordial leads other than V_{10} (over the dorsal spine) are not commonly used.

Telemetry-based ECG recordings commonly are used in exercise testing (see the previous section, Exercise Testing) and in monitoring of critical patients in hospital settings. The lead systems used are often similar to those used for Holter ECG recordings; however, the degree of artifact that occurs during exercise is considerable. Those interested in consistent recordings must experiment with various electrode positions and lead systems.

The orientation, amplitude, and duration of the ECG waveforms depend on many factors, including the age of the horse,[303,386] the lead examined, the size of the cardiac chambers, the degree of training, and even the phase of ventilation.[367,368] The principal use of the ECG is to diagnose the heart rhythm, because the ECG is less sensitive for detecting cardiomegaly, especially in horses with mild to moderate heart enlargement. A 381
normal ECG does not exclude heart disease; moreover, the ECG is not a test of myocardial function. One 382
should undertake a systematic approach to ECG analysis and compare the results with reference values (Table 8-4).

Figure 8-15 Examples of extrasystoles. Atrial *(P' at top)* and ventricular *(bottom)* extrasystoles in a mare with heart failure, sinus tachycardia, and premature beats. The recordings are from a 24-hour tape-recorded (Holter) electrocardiogram. Two transthoracic leads recorded simultaneously. The waveforms are indicated. The dark circles indicate the premature complexes. The P-R interval of the atrial premature complex is longer because of physiologic refractoriness in the atrioventricular node. The ventricular ectopic follows the sinus P wave (late diastolic) but discharges the ventricle before the sinus impulse can cause a normal QRS complex. The T wave of the ventricular extrasystole is abnormal (secondary T wave change). Paper speed is 25 mm/sec.

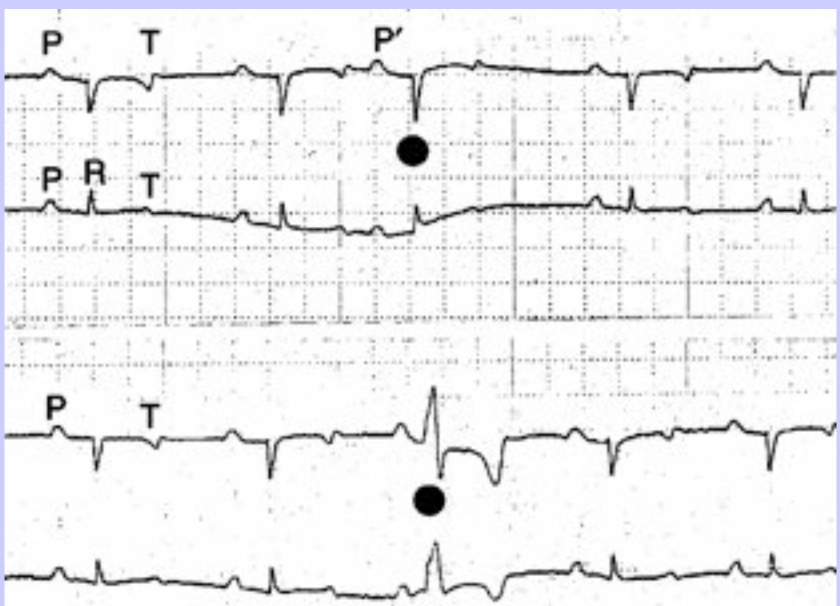


TABLE 8-4 Electrocardiography: Approximate Limits for Normal Frontal Plane Leads

VARIABLE	MAXIMAL VALUE	COMMENTS
Heart rate	40 beats/min	Resting mature horses; higher in foals, colts, and ponies
Cardiac rhythm	—	Sinus mechanisms, sinus arrhythmia, vagal-induced first- and second-degree atrioventricular block*
P wave	0.16 seconds	Atrial repolarization (Ta wave) may make measurement difficult.
P-R interval	0.48 seconds	Varies; longer when vagal tone is high.
QRS complex	0.14 seconds	May vary with the size of the heart (often longer in the base-apex lead).
QT interval	0.575 seconds	Inversely related to the heart rate
R wave lead I	0.85 mV	
R wave leads 2, aV_F	2.3 mV	
Frontal axis	0–100 degrees	Axis varies in foals and yearlings.

Technical aspects: paper speed, calibration, and lead(s)
Artifacts: electric, motion, twitching, and muscle tremor
Heart rate per minute: atrial and ventricular
Cardiac rhythm: atrial, atrioventricular conduction sequence, and ventricular conduction
Arrhythmias
Site or chamber of abnormal impulse formation, myocardial fibrillation, or conduction disturbance
Rate of abnormal impulse formation
Conduction of abnormal impulses
Patterns or repeating cycles
P wave: morphology, duration, amplitude, and variation
P-R interval: duration, variation, and conduction block (of P wave)
QRS: morphology, duration, and amplitude
Frontal plane mean electric axis
ST segment: depression or elevation
T wave: changes in morphology or size; QT interval
Miscellaneous: electrical alternans, synchronous diaphragmatic contraction

* When evaluating the electrocardiographic rhythm, one should consider the following points:

Atrial depolarization generates the P wave. Normal activation proceeds from right to left and craniad to caudad, leading to positive P waves in left-right lead I and also in craniocaudal leads II and aV_F.[8,11] The normal P wave is notched or bifid; however, one may encounter single-peaked, diphasic, and polyphasic P waves in normal horses. A negative/positive P wave often is recorded if the focus of pacemaker activity shifts to the caudal right atrium near the coronary sinus (Figure 8-16). The initial peak of the common bifid P wave reportedly is caused by depolarization of the middle and caudal one third of the right atrium.[6] The second peak represents activation of the atrial septum and the medial surface of the left atrium. The P wave peaks can be subdivided with P_1 reported to be as high as 0.25 mV (mean of 0.14) and the second peak, P_2, reported to be as high as 0.5 mV (mean of 0.28).[363] Subtle differences exist even among breeds of horses. The P wave 382
morphology can change cyclically with waxing and waning of vagal tone during sinus arrhythmia. During 383
tachycardia, the P wave shortens, becomes more peaked, and is followed by a prominent atrial repolarization (Ta) wave that deviates the PQ segment downward. Such features make the diagnosis of atrial enlargement by electrocardiography difficult.

Figure 8-16 P waves of the horse are demonstrated. On the left is a normal, bifid P wave morphology with two distinct peaks (designated as *P1* and *P2*) and also a physiologic second-degree atrioventricular block *(arrow)*. The center panel demonstrates a negative/positive P wave of coronary sinus origin. This is a normal variation. The right panel shows increased amplitude P waves recorded in a horse after conversion from atrial fibrillation. The second peak is particularly large and may indicate atrial enlargement; however, such voltage criteria correlate poorly with cardiomegaly in horses. Echocardiography is a more accurate method for evaluating atrial size. Lead 2 paper speed is 25 mm/sec.

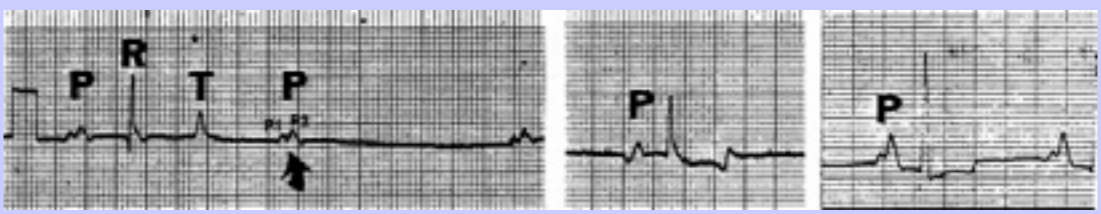

Figure 8-17 Multiple lead recordings in a normal horse. The varying configuration of the P-QRS-T complexes across the leads is notable.

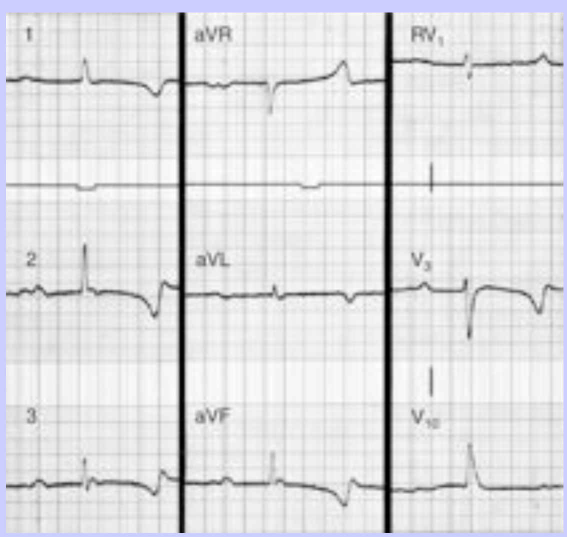
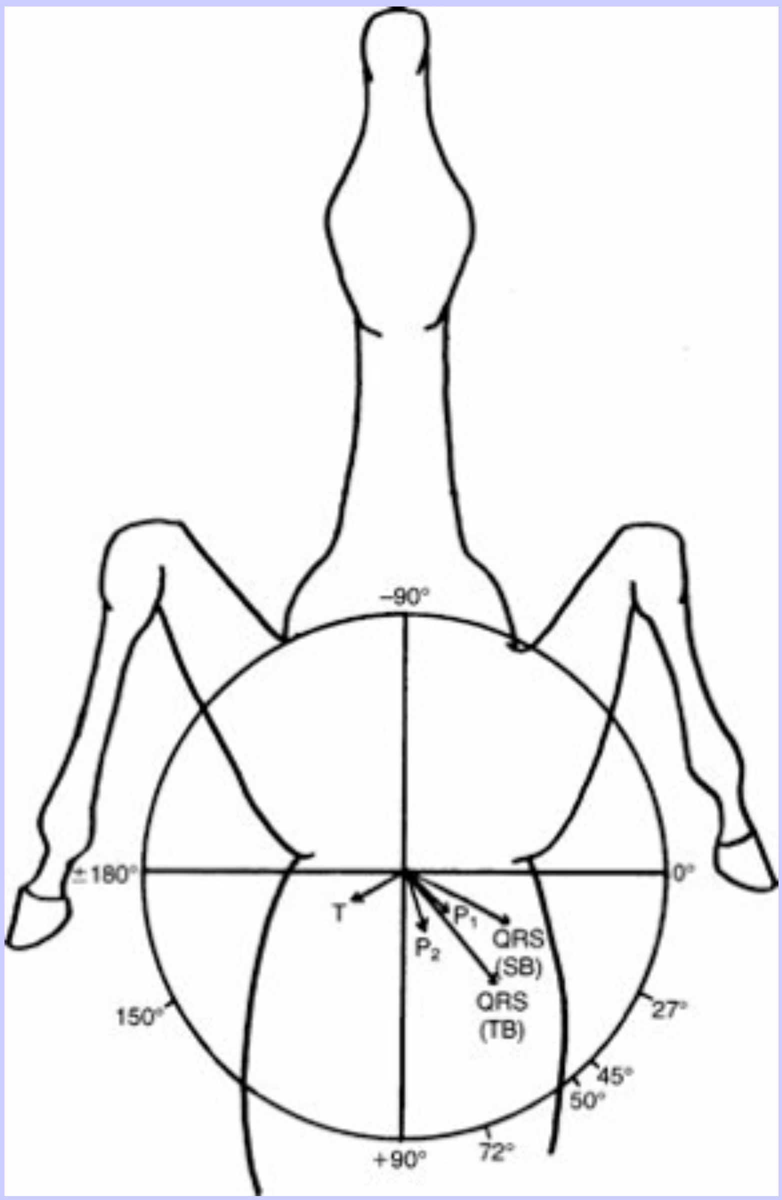


One estimates the time required for conduction across the atrioventricular node and His-Purkinje system by measuring the P-R interval. Because physiologic atrioventricular block is so common, significant variation exists in the P-R interval even within the same horse; thus normal maximal values for the P-R interval are difficult to state. Values that persistently exceed 0.5 seconds are probably abnormal. Variation in the P-R interval usually is not related to changes in ventilation[42] but often is correlated with changes in blood pressure and baroreceptor activation.[68]

The morphology of the QRS complex varies. The complete penetration of the conduction system into the free walls of the ventricle causes these chambers to be activated simultaneously with a burst of depolarization, which cancels much of the divergent electromotive forces.[6,7] Consequently, the normal electric axis may vary and the amplitude of the QRS complex can be small in the frontal plane leads. A substantial dorsally oriented vector causes a prominent positive terminal deflection in lead V_{10}, whereas the (negative electrode) right base to (positive electrode) left apex lead exhibits a prominent S-wave (Figure 8-17). The normal slur in the ST segment makes determination of QRS duration difficult in many horses.[35,393] The mean amplitude for the R wave in lead II for normal racehorses is about 0.8 to 1.1 mV.[*] Clinical experience suggests that R wave amplitudes exceeding 2.2 mV in lead II or 1.7 mV in lead I are often abnormal. But occasionally the R wave amplitude in a normal horse exceeds even these limits.

Figure 8-18 Diagram of the normal frontal plane lead axis. The predominant vectors for the QRS complex in Standardbred *(SB)* and Thoroughbred *(TB)* horses are indicated. The orientation of the two components of the normal P wave (*P1* and *P2*; see Figure 8-16) differ slightly. (From Fregin GF: The cardiovascular system. In Mansmann RA, McAllister ES, Pratt PW, editors: *Equine medicine and surgery,* Santa Barbara, Calif, 1982, American Veterinary Publications.)



One can inspect the frontal plane leads to estimate the mean electric axis of depolarization, the average wave of depolarization (Figure 8-18). This determination usually is reported by direction using a quadrant orientation (right or left; cranial or caudad) or is stated in degrees (lead I is 0 degrees; lead II is 60 degrees; lead aV_F is 90 degrees; lead III is 120 degrees; lead aV_R is minus 150 degrees; and lead aV_L is minus 30 degrees). One can estimate the general direction of the QRS axis quickly by surveying the height of the R waves in the frontal leads and selecting the lead with the greatest net-positive QRS complex. The axis in foals and yearlings varies and frequently is oriented craniad, whereas the frontal axis in most mature horses is 383 directed left-caudad. Abnormal axis deviations have been observed with cardiomegaly, cor pulmonale, 384 conduction disturbances, and electrolyte imbalance.[389]

Following the ventricular activation, the electrocardiograph records repolarization of the ventricles. This period is measured from the end of the QRS complex (the J point) and extends to the end of the T wave.[35,362,394] The T wave vector most often is directed toward the right caudal quadrant, resulting in a positive T wave in lead III and a negative or isoelectric T wave in lead I in resting horses.[363] Although some clinical surveys have suggested that abnormalities of the ST-T indicate cardiac dysfunction in performance animals, significant deviation of the ST segment and increased amplitude of the T wave are anticipated even in normal horses during exercise or even with excitement-induced tachycardia. Simply no unanimity of opinion exists regarding T waves in horses, nor does compelling evidence that T-wave abnormalities can be interpreted consistently. Progressive J point or ST segment deviation in the horse with hypovolemia or shock may indicate myocardial ischemia, whereas enlargement of the T wave may develop with myocardial hypoxia or hyperkalemia.

Diagnosis and management of cardiac arrhythmias are discussed later in this chapter.

8.4.3 THORACIC RADIOGRAPHY

The use of thoracic radiography in the evaluation of the equine heart has severe limitations because of the large size of the mature horse and the ability to obtain only a standing lateral thoracic radiograph in all except the smallest neonatal foals.[105] Although one can obtain recumbent lateral, and on occasion ventrodorsal or dorsoventral, projections on small neonatal foals, the stress of restraint or requirement for heavy sedation can contraindicate such positioning. Thoracic radiographs may be useful to identify areas of pulmonary or pleural disease and assist in the differential diagnosis of respiratory problems.

One may detect gross changes in cardiac size and shape in a lateral thoracic radiograph of a foal or horse with significant cardiomegaly.[105,297,395–397] A normal thoracic radiograph does not indicate necessarily that the heart is normal in size. Mild to moderate increases in the size of the cardiac chambers may go undetected, particularly in adult horses. Generalized enlargement of the cardiac silhouette occurs in cases of significant pericardial effusion or with CHF (Figure 8-19). One may detect dorsal displacement of the trachea in some horses with left atrial (LA) and LV enlargement. In some horses with LA enlargement, the caudodorsal border of the cardiac silhouette bulges caudally. One may detect increased contact between the ventral border of the heart and the sternum with RV enlargement, but this is usually difficult to appreciate. A 50% decrease in the spinotracheal angle (the angle between the dorsal border of the trachea and the ventral border of the adjacent thoracic vertebrae) was demonstrated in young horses with cardiomegaly caused by congenital cardiac disease.[105]

Evaluation of the pulmonary vasculature and pulmonary parenchyma is also difficult and depends on radiographic technique. Occasionally one can observe enlarged pulmonary vessels and increased radiolucency of the pulmonary parenchyma associated with pulmonary overcirculation (as with septal defects); the opposite is also true in congenital right-to-left shunts. Pulmonary edema causes generalized increased radiopacity, particularly in the hilar regions; the characteristic air bronchograms are more readily identifiable in the hilar regions when alveolar edema is present.

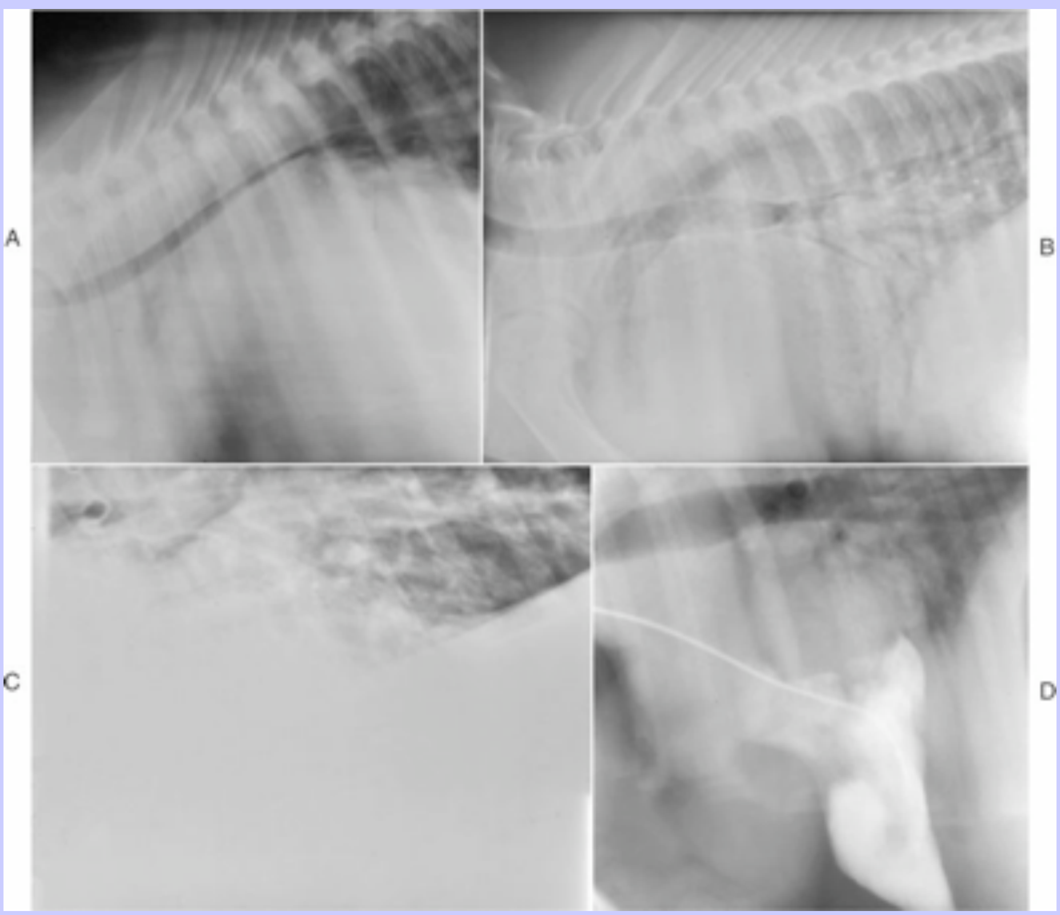
Angiocardiography is only practical in foals less than 250 lb and usually requires general anesthesia, which may be contraindicated in the foal with a severely compromised cardiovascular system. Selective and nonselective positive contrast angiocardiograms have been performed in foals and adult horses (see Figure 8-19),[146,395,398] but these techniques have been replaced almost exclusively by echocardiography and Doppler studies.

Nuclear medicine imaging has been developed in some equine referral institutions and is likely to become more widespread in the future because it provides another method of assessing cardiac function. First pass nuclear angiocardiography is most widely used and permits the visualization of the cardiac chambers during sequential phases of the cardiac cycle.[105] Application of first pass studies may be useful for identifying cardiac shunting, but again this diagnosis is attained more simply by echocardiography.

8.4.4 ECHOCARDIOGRAPHY

Ultrasound is the mechanical vibration of sound waves within a medium at frequencies greater than 20,000 cycles/sec. These inaudible sound waves follow the laws of optics, can be transmitted through tissue, and also can be refracted and reflected. This last property permits the clinician to image the heart and other organs.[399] Echocardiography is the application of ultrasound diagnostics to the heart. When combined with Doppler studies,[400] echocardiography has evolved to become the most important diagnostic study currently available for evaluation of the equine heart.[*] Successful examination of the equine heart requires the use of crystals that vibrate at frequencies between 2 to 5 MHz, a detailed knowledge of ultrasound anatomy, thorough appreciation 384
of equine cardiac diseases, and technical skills with imaging and instrumentation. Ultimately, a thorough 385
echocardiographic examination yields information about the presence and nature of heart lesions, the size of the heart and great vessels, ventricular function, valvular function, blood flow, and the relevant hemodynamics about a cardiac lesion.

Figure 8-19 Thoracic radiography. **A,** Significant cardiomegaly in a Quarter Horse foal with complex congenital heart disease, including multiple ventricular septal defects. **B,** Cardiomegaly and alveolar pulmonary edema in a filly with mitral regurgitation and left-sided congestive heart failure. **C,** Increased pulmonary density and pleural effusion in a Standardbred gelding with atrial fibrillation, atrioventricular valvular regurgitation, myocardial failure, and biventricular congestive heart failure. **D,** Angiocardiogram obtained from an Arabian foal with pulmonary atresia and a large ventricular septal defect (pseudotruncus arteriosus). Contrast medium was injected in the left ventricle, and this medium opacifies a dilated, overriding aorta. Right-to-left shunting across the ventricular septal defect results in dilution of contrast medium.



The essential principle of echocardiography is straightforward: When one directs ultrasound into the chest and toward the heart, some of the sound energy reflects back to the transducer. This occurs because the echo beam encounters tissue interfaces with different acoustic impedance, such as collagen and blood, that reflect the ultrasound. A handheld transducer acts to send and receive ultrasound.[409,449] The echocardiograph computer is capable of determining the spatial orientation and distance of the returning echoes, processing the signals, and displaying an image of the heart. The image usually is displayed, by convention, with that part of the heart 385
closest to the transducer at the top of the display and adjacent to the transducer artifact. Two imaging modalities, 388
the M-mode (motion) and two-dimensional (B-mode or cross-sectional) formats are in general use. If Doppler studies are included, one can detect blood flow relative to the two-dimensional and M-mode images (Box 8-8, Figure 8-20; see also Figure 8-6).[139,266] One can use M-mode, two-dimensional, contrast echo, and Doppler studies to identify pathologic conditions, quantify the heart size and mass,[49,50,403] estimate ventricular function, and identify effects of training.[446,447] One can apply the technique to assess the fetal heart.[450]

8.4.4.1 BOX 8-8 INTERPRETATION OF DOPPLER AND ECHOCARDIOGRAPHIC STUDIES

8.4.4.1.1 Cardiac Rhythm

Arrhythmias alter cardiac motion and velocity signals.

8.4.4.1.2 Identification of Atria, Cardiac Septa, Ventricles, Inlet and Outlet Valves, Great Vessels, Veins

Presence, absence, hypoplasia, or atresia of anticipated structures.

Identification of cardiac mass lesions and thrombi.

Identification of obvious lesions (e.g., septal defect, thick valve).

8.4.4.1.3 Cardiac Mensuration

Ventricular dilation or hypertrophy

Atrial enlargement

Aortic or pulmonary artery dilation or attenuation

Abnormally small chamber or great vessel

8.4.4.1.4 Global Left Ventricular Systolic Function

Subjective analysis of radial shortening (short-axis view).

M-mode fractional shortening (normal usually between 32% and 55%).

Reduced fractional shortening: Rule out dilated cardiomyopathy, chronic valvular heart disease, myocarditis, and myocardial necrosis (e.g., monensin); atrial fibrillation (mild depression); and prolonged ventricular tachycardia. General anesthesia and sedative drugs can decrease fractional shortening.

Increased fractional shortening: Rule out volume overload (especially mitral regurgitation or aortic regurgitation), sympathetic activity, and recent exercise.

8.4.4.1.5
Mitral and Tricuspid Valves

Identification of valve cusps, support apparatus, and motion during cardiac cycle.

Reduced opening or leaflet separation (M-mode E-F slope): Rule out stenosis, vegetation, decreased atrioventricular flow, and aortic regurgitant jet-striking septal mitral leaflet.

Increased echogenicity: Rule out vegetation, degenerative thickening, and dysplasia.

Diastolic mitral fluttering: Rule out aortic insufficiency.

Diastolic tricuspid valve fluttering: Rule out ventricular septal defect and ruptured aortic sinus aneurysm.

Systolic mitral fluttering: Rule out atrioventricular insufficiency.

Chaotic motion: Rule out arrhythmias and ruptured chordae tendineae.

Prolapse into the atrium: Rule out degenerative disease, ruptured chordae tendineae, connective tissue disorder, bacterial endocarditis, and malformation.

Premature (diastolic) closure: Rule out severe semilunar valve insufficiency or long P-R interval.

Delayed (systolic) closure: Rule out LV[*] failure (high end-diastolic pressure).

Increased mitral E point to septal distance: Rule out LV dilation, cardiac failure, and aortic regurgitant jet-striking valve.

Cleft: Rule out endocardial cushion defect.

8.4.4.1.6
Aortic/Pulmonic Valves

Identification of valve leaflets and motion during cardiac cycle.

Narrowing of the LV or RV outflow tracts: Rule out stenosis and hypertrophy.

Diastolic fluttering: Rule out semilunar valve insufficiency.

Systolic fluttering: normal or high-flow state.

Increased echogenicity (focal or diffuse): Rule out bacterial vegetation, degeneration, and congenital lesion.

Prolapse into ventricle: Rule out degenerative (connective tissue) disease, endocarditis, and subaortic septal defect.

Lack of systolic separation: Rule out low cardiac output, arrhythmia, stenosis, and endocarditis.

Premature (midsystolic) closure: Rule out outflow tract obstruction and ventricular septal defect.

Systolic doming: Rule out congenital valve fusion/stenosis and endocarditis.

8.4.4.1.7
Left Ventricular Wall and Chamber

Hypertrophy: Rule out hypertension, aortic or subaortic stenosis, hypertrophic cardiomyopathy, myocardial infiltration, and volume depletion (pseudohypertrophy).

Dilation: Rule out causes of volume overload, cardiomyopathy, valvular disease, left-to-right shunts, and atrioventricular fistula.

Hypokinesis: Rule out myocardial failure, anesthesia, myocarditis, myocardial necrosis, and ischemia or fibrosis (regional wall motion defect).

Hyperkinesis: Rule out mitral or aortic insufficiency, volume overload (e.g., left-to-right shunts), sympathetic stimulation, and hypertrophic cardiomyopathy, with or without stenosis.

Dyskinesis: Rule out cardiomyopathy, ischemia, infarct, thrombotic disease, and toxic insult (e.g., ionophore).

Giant papillary muscle: Rule out hypertrophy, and atrioventricular valve dysplasia.

Hypo- and hyperechogenicity: normal (variation), infarct, fibrosis, dissection, septal defect.

8.4.4.1.8
Ventricular Septal Wall

Hypertrophy: Rule out aortic or pulmonic stenosis, pulmonary or systemic hypertension, tetralogy of Fallot, and truncus arteriosus.

Hyperkinesis: As per LV chamber.

Hypokinesis: As per LV chamber. Rule out RV pressure or volume overload.

Paradoxic or flattened motion: Rule out moderate to severe RV volume or pressure overload, such as atrioseptal defect, tricuspid regurgitation, and pulmonary hypertension.

Echo “dropout”: Rule out septal defect and aneurysm.

Discontinuity of septum and aortic root: Rule out septal defect, tetralogy of Fallot, pulmonary artery atresia, and truncus arteriosus.

8.4.4.1.9
Right Ventricular Wall and Chamber

Hypertrophy: Rule out pulmonary hypertension, pulmonic stenosis, and tetralogy of Fallot.

Dilation: Rule out tricuspid insufficiency, chronic RV pressure overload, and atrial septal defect.

8.4.4.1.10
Left Atrium

Decreased size: Rule out right-to-left shunting and hypovolemia.

Dilation: Rule out mitral regurgitation or stenosis, cardiomyopathy, left-side heart failure, and left-to-right shunts.

Increased density: Rule out thrombus or tumor.

8.4.4.1.11 Right Atrium

Dilation: Rule out tricuspid regurgitation or stenosis, cardiomyopathy, right-side heart failure, and atrial septal defect.

Increased density: Rule out tumor and thrombus.

8.4.4.1.12 Atrial Septal Wall

Significant bowing: Rule out volume overload of one atrium.

Echo “dropout”: Rule out septal defect.

8.4.4.1.13 Pulmonary Artery

Absence: Rule out atresia.

Dilation: Rule out pulmonic stenosis, intracardiac left-to-right shunt, patent ductus arteriosus, pulmonary hypertension from any causes including left-sided congestive heart failure.

8.4.4.1.14 Aorta

Decreased diameter: Rule out low cardiac output.

Dilation: Rule out subaortic or aortic stenosis, tetralogy of Fallot, pulmonary artery atresia, patent ductus arteriosus, systemic hypertension, truncus arteriosus, and aortic insufficiency.

Aneurysm: Rule out congenital lesion, or endocarditis or vascular disease as cause.

8.4.4.1.15 Pericardium

Rule out pericardial effusion, constriction, fibrinous reaction or fronds, or mass lesion.

Rule out pulmonary or mediastinal abscess.

8.4.4.1.16 Doppler Flow Studies (Color Coded, Pulsed Wave, Doppler, Continuous Wave)

Estimation of cardiac output (flow-velocity integral × vessel cross-sectional area × heart rate).

Estimation of ventricular function (from aortic and pulmonary artery acceleration time or from tissue Doppler imaging).

Estimation of intracardiac pressures (from continuous wave velocity measurements across incompetent, stenotic valves or septal defects).

Detection of valvular regurgitation (abnormal direction, turbulent flow signals).

Detection of valvular stenosis (abnormal high-velocity, turbulent flow signals).

Detection of intracardiac shunting (abnormal turbulent flow signals)

* *LV,* Left ventricle; *RV,* right ventricle.

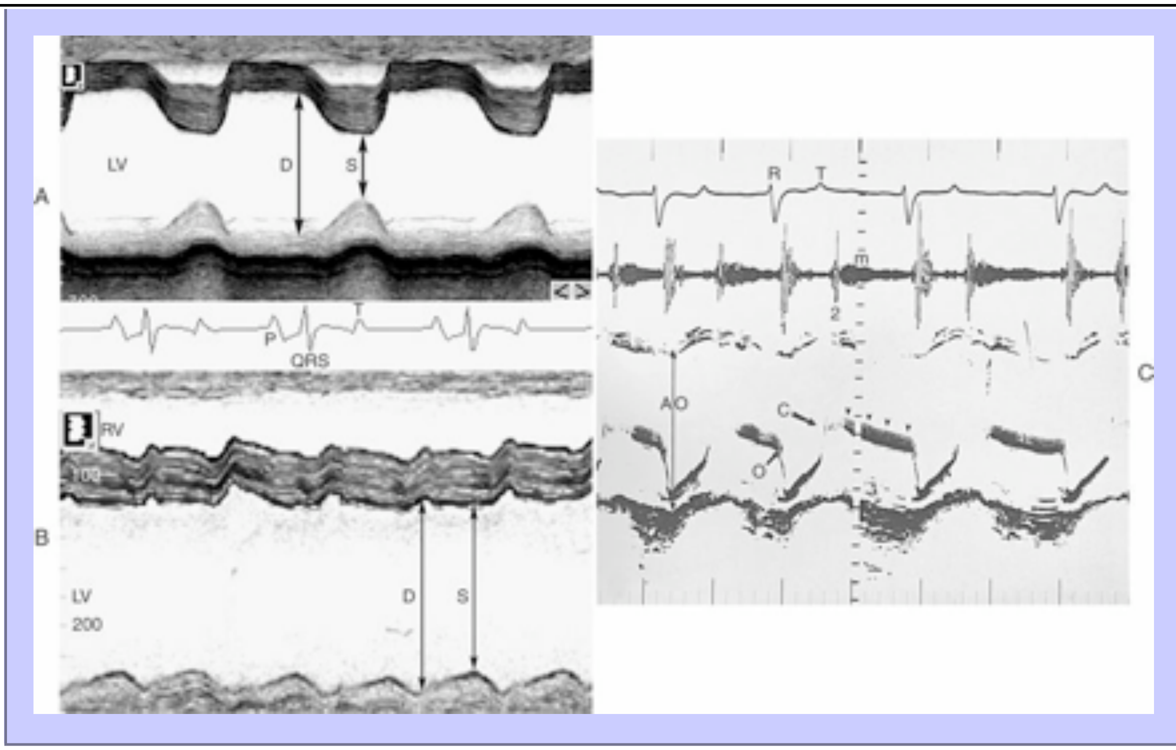
Modified from Bonagura JD, Herring DS, Welker F: Echocardiography, *Vet Clin North Am Equine Pract* 1:311, 1985.

The M-mode echocardiogram is a single-crystal ice pick image of the heart (see Figure 8-6).[13,14,53,451] The movement of the cardiac structures (vertical axis) is displayed over time along the horizontal axis. The ECG waveforms provide a timing reference, and the depth of the cardiac structures from the transducer (y-axis) is displayed in centimeters. Visualization of the characteristic movements of cardiac structures permits the experienced viewer to evaluate and quantify cardiac anatomy and function (see Figure 8-20). The high sampling rate of the M-mode study makes it excellent for visualizing rapidly vibrating structures, such as the oscillating mitral leaflet in aortic regurgitation.[128]

The two-dimensional echocardiogram generates a cardiac field by mechanically or electrically sweeping one or more piezoelectric crystals across the heart (Figure 8-21).[*] In conventional transthoracic echocardiography, the operator directs the imaging probe by hand to achieve a suitable tomographic plane. The pie-shaped image obtained has depth and breadth but has no significant thickness. Accordingly, the operator must use different image planes to interrogate the three-dimensional heart. These imaging planes are designated long-axis (sagittal), short-axis (coronal), apical (when the transducer is near the left apex), and angled (hybrid) views. The two-dimensional field is updated constantly to visualize cardiac motion in real time and occurs at typical sampling rates of 20 to 40 frames/sec with the update rate inversely related to penetration depth and angle of field. Fully digital echocardiographs can display much faster frame rates, often exceeding 60 frames/sec. In most cases the two-dimensional study is watched in real-time and also recorded on videotape or digitally for subsequent playback and analysis. Human interpretation generally is limited to 32 frames/sec, so that recordings made at higher frame rates require slow motion playback for detailed analysis. Transesophageal echocardiography has been used in horses[448] but requires specially made endoscope-mounted transducers and is most practical in anesthetized or sedated horses because of the fragile (and expensive) nature of the probe.

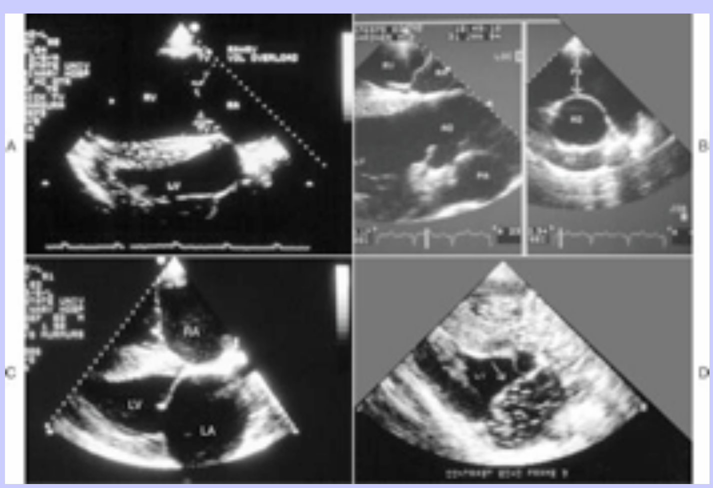
Doppler echocardiography relies on the Doppler principle to measure the direction and velocity of red blood cells in the heart (Figure 8-22; see also Figure 8-6).[*] In Doppler echocardiography, a portion of the ultrasound emitted by the transducer strikes moving red blood cells. These targets reflect ultrasound to the transducer. Because the red blood cells constitute a moving source of (reflected) ultrasound, the returning sound waves attain a frequency that is slightly different from that originally transmitted (the carrier frequency). When the echocardiograph unit records the Doppler frequency shift, calculation of red blood cell velocity and direction relative to the transducer is possible. The information is displayed as a Doppler spectrum showing time along the horizontal axis, flow direction relative to the transducer as above (toward) or below (away from) a zero baseline, 388
and calculated red blood cell velocity along the y-axis. Thus pulsed Doppler methods measure direction and 389
velocity of red blood cells within a discrete area of the heart or circulation. Disturbed flow, as might be recorded across a regurgitant orifice or VSD, results in a high velocity and broadened velocity spectrum.

Figure 8-20 M-mode echocardiography. **A,** M-mode tracing demonstrating a hyperdynamic left ventricle *(LV)* in a horse with acute mitral regurgitation. The significant change in left ventricular dimensions from diastole *(D)* to systole *(S)* is notable and is typical of volume overloading with preserved ventricular function. Furthermore, the reduced resistance to ejection of blood into the left atrium enhances ventricular shortening. Depth calibration in millimeters is shown on the left. **B,** Recording through the ventricles demonstrating decreased contractility with a reduced left ventricular shortening fraction. This pattern of contraction can be caused by myocarditis, myocardial injury (e.g., monensin), idiopathic dilated cardiomyopathy, chronic volume overload, protracted ventricular tachycardia, or administration of negative inotropic drugs. Depth calibration in millimeters is shown on the left. (*RV,* Right ventricle.) **C,** Recording from a horse with aortic regurgitation and atrial fibrillation, demonstrating fine diastolic fluttering of an aortic valve leaflet *(small arrows)*. The aortic root *(AO),* valve opening *(O)*, and valve closing *(C)* are indicated. The murmur (m) of aortic regurgitation is evident in the phonocardiogram above. First *(1)* and second *(2)* heart sounds are labeled. Diastolic fluttering of the mitral valve (most common), aortic valve, ventricular septum, or walls of the aortic root may be observed in horses with this hemodynamic abnormality. The M-mode sampling rate (approximately 1000 pulses/sec) is ideal for detecting these high-frequency events.



Color-coded Doppler imaging is a more refined example of pulsed wave technology whereby flow toward the transducer is coded in red and flow away is represented in blue. Calculated velocity is displayed in relative shades of these colors and green or yellow are added to the flow mapping to identify turbulence. Color coding permits superimposition of flow information onto the two-dimensional image (Figure 8-23). Although substantial technical challenges exist in terms of penetration and frame rate, color Doppler imaging is useful in horses because one can screen a large area of the heart for flow disturbances. For example, finding a jet of MR using color Doppler imaging is much easier than with other Doppler methods. A pivotal limitation of color Doppler regards temporal resolution. Depending on the system used, the frame rates of interrogation can be slow 389
(often <10 frames/sec). Thus timing of the flow event is mandatory using spectral Doppler or by invoking the M- 390
mode cursor and recording the event by color M-mode echocardiography. Timing prevents the clinician from misinterpreting normal backflow signals related to valve closure or diagnosing a diastolic flow event as systolic.

Figure 8-21 Two-dimensional echocardiograms. **A,** Long-axis image from the right thorax in a 12-year-old Quarter Horse gelding demonstrating significant right ventricular and right atrial dilation following tricuspid regurgitation and elevated pulmonary artery pressure. In this case a tumor that obstructed flow in the main pulmonary artery caused the pulmonary hypertension. The ventricular septum is flat and bulges slightly into the left ventricle. **B,** Images of the ascending aorta and pulmonary artery obtained from the right hemithorax *(left panel)* and left cranial hemithorax. An evaluation of the pulmonary artery diameter relative to the aorta is useful when identifying pulmonary hypertension. **C,** Biatrial dilation in a Thoroughbred colt with mitral regurgitation, pulmonary hypertension, atrial fibrillation, and congestive heart failure. Both atria are rounded and appear turgid. The cause of mitral disease in this case was idiopathic lymphocytic-plasmacytic mitral valvulitis. (*RA,* Right atrium; *LV,* left ventricle; *LA,* left atrium.) **D,** Contrast echocardiogram demonstrating right-to-left shunting at the level of the foramen ovale in a foal with severe respiratory disease. The saline generates echocontrast, opacifies the right atrium and right ventricle and visibly fills the left atrium *(arrows)* although the left ventricle has not yet been opacified. This technique is easy and practical for demonstrating right-to-left shunts across the cardiac septa.

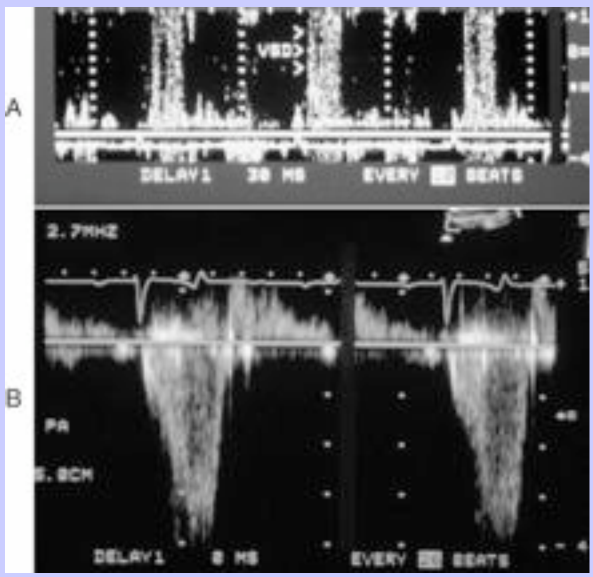


Pulsed wave spectral and color Doppler techniques can provide accurate information about the location of flow disturbances but cannot measure high-velocity flow faithfully. High-velocity flow occurs as red blood cells are ejected from higher to lower pressure zones across incompetent valves, stenotic valves, and intra- and extracardiac shunts (provided that a pressure difference exists across the defect). In general, once velocities exceed about 2.5 m/sec in either direction, part of the returning signal is displayed in the incorrect direction. This problem is called signal aliasing[225] (see Figure 8-22, *A*). To quantify high-velocity flow, one must invoke a third modality, high pulse-repetition-frequency Doppler or continuous wave Doppler. Continuous wave Doppler has virtually unlimited ability to record high velocity but does not provide the spatial discrimination found in pulsed 390
wave Doppler modalities. Recording disturbed flow accurately has clinical value. The appearance of a flow 391
disturbance can provide qualitative information about the severity of a lesion (see later in this chapter). Furthermore, one can estimate the pressure difference between the source and the sink of a high-velocity jet by the modified Bernoulli equation, in which pressure drop in millimeters of mercury equals $4V^2$ (where maximal velocity, V, is measured in meters per second by continuous wave Doppler). If, for example, a peak velocity of 4.8 m/sec is recorded across a VSD, and if the systolic systemic arterial blood pressure is determined noninvasively to be 125 mm Hg, the estimated RV systolic pressure would be calculated as follows:

$$\begin{gathered}\text{Pressure drop} = 4 \times 4.8^2 = 92 \text{ mm Hg}\\ \text{Estimated LV systolic pressure} = 125 \text{ mm Hg}\\ \text{Estimated RV systolic pressure} = 125 - 92 = 33 \text{ mm Hg}\end{gathered}$$

These findings indicate a restrictive septal defect, a lesion unlikely to cause difficulties for the horse except at highest levels of performance.

Figure 8-22 Spectral Doppler echocardiograms. **A,** Pulsed wave Doppler study from a horse with a ventricular septal defect. The baseline of zero flow has been shifted to the bottom. A high-velocity, turbulent systolic jet is recorded but cannot be quantified faithfully. The signal wraps around the baseline (signal alias). Calibration dots are 20 cm/sec. **B,** A continuous wave Doppler study from a filly with tetralogy of Fallot. The high-velocity flow pattern across the stenotic pulmonary artery is recorded as a negative signal below the zero baseline. Calibration dots are 1 m/sec. The jet velocity exceeds 4 m/sec.



Echocardiography is most useful in evaluating congenital heart disease, heart murmurs, pericardial diseases, heart failure, and cardiac arrhythmias. Ultrasound also can identify other lesions of the lung, pleural space, or mediastinum that may masquerade as heart disease.[94,455] One can determine accurately the source of a pathologic cardiac murmur, the size and function of the heart, and the overall effect of a cardiac lesion by a complete echocardiographic and Doppler examination. A normal echocardiogram and Doppler study in a horse with a cardiac murmur is a favorable finding, suggesting a functional basis for the murmur. Conversely, identification of an abnormal flow pattern with associated cardiomegaly or abnormal ventricular function may indicate a high risk or limitation for work. As with all diagnostic studies, results can be ambiguous, particularly regarding the tricuspid valve, because physiologic TR, silent to auscultation, is detectable by Doppler studies in many clinically normal horses. Contrast echocardiography[456], whereby saline is used to delineate the path of blood flow, is especially useful for the detection of right-to-left shunts in foals, including patent foramen ovale (see Figure 8-21). Reference values for ventricular chamber size, wall thickness, and LV shortening fraction

have been published,[51,206,220,266–268,426] and Table 8-5 gives some representative data.[220,266] Clinical applications of echocardiography are illustrated later in this chapter.

8.4.5 CARDIAC CATHETERIZATION

A large body of literature is derived from catheterization studies of the standing, exercising, anesthetized, and diseased horses.[*] In the clinical setting, however, cardiac catheterization has been replaced largely by Doppler echocardiography. The clinician can obtain anatomic, flow, and pressure estimates noninvasively, safely, and more readily with ultrasound studies. Some indications for cardiac catheterization in clinical patients remain, particularly when one requires accurate measurement of pulmonary artery pressure or entertains a diagnosis of occult constrictive pericardial disease.

Hemodynamic variables one can measure or calculate by catheterization include arterial blood pressure, pulmonary arterial and pulmonary artery occlusion (capillary wedge) pressure, intracardiac pressures, central venous pressure, CO, systemic and pulmonary vascular resistances, and arteriovenous oxygen difference. Normal values for these depend on the methods used for measurement, the head and body position of the horse, and the effects of administered tranquilizers, sedatives, or anesthetic agents. One should appreciate some general principles of hemodynamics. 391

Figure 8-23 Black-and-white representations of color Doppler echocardiograms demonstrating mapping of blood flow through the heart. **A,** Perimembranous ventricular septal defect in a foal *(arrow)*. The flow pattern was coded red and aliased as the velocity increased across the defect. **B,** Wide spray of mitral regurgitation with flow moving from left ventricle *(LV)* into the left atrium *(LA)* in a horse with mitral valve prolapse. (*RV,* Right ventricle; *RA,* right atrium.) **C,** Color M-mode study from a horse with tricuspid regurgitation. The bright systolic flow pattern, following the QRS of the electrocardiogram, was mapped as turbulence in the color study. This is an excellent method for timing abnormal flow events.

Pressures on the left side of the circulation include systemic arterial, LV, and LA pressures. Systemic arterial pressure is linked closely to LV function, impedance to blood flow in the aorta, systemic vascular resistance, and heart rate. Measurement of arterial blood pressure has been described previously. Peak systolic pressures in the aorta and left ventricle should be essentially equal, and a substantial difference between these values would indicate an obstruction to outflow, a most rare condition in horses. LV diastolic pressure reflects diastolic function and filling and the ability of the ventricle to empty its stroke volume. The reported diastolic pressure is usually the end-diastolic pressure (typically 12 to 24 mm Hg in standing animals), which is higher than the early

(often subatmospheric) minimal diastolic LV pressure. Horses and ponies have higher ventricular end-diastolic pressures than do human beings or dogs.[21,24,214,468] Exercise is a physiologic cause of increased LA and ventricular end-diastolic pressures.[278,459,462,481–484] Elevation of resting LV end-diastolic pressure generally indicates reduced myocardial contractility, ventricular failure, LV volume overload as with mitral or aortic regurgitation, myocardial infiltration (lymphoma, amyloid), or pericardial constraint or increased ventricular wall stiffness.

One can obtain the pulmonary arterial pressures by percutaneous placement of a flow-directed catheter from the jugular vein to the pulmonary artery. Inflating the balloon tip to occlude the pulmonary artery transiently and wedge the distal catheter tip may be possible. One can use such pulmonary capillary wedge pressures to estimate pulmonary capillary and venous pressures as well as LA pressure.[233,462,464,482,485] The pulmonary artery pressures in standing mature horses are considerably lower than are those of the aorta because of the lower resistance encountered in the pulmonary vascular tree. Mean pulmonary artery pressure is higher in the newborn foal and decreases significantly during the first 2 weeks of life because of decreased pulmonary arteriolar 392

393 resistance.[233] Normal pulmonary arterial pressures are 35 to 38 mm Hg systolic and 14 to 22 mm Hg diastolic. Pulmonary pressures increase dramatically with increased CO as encountered during exercise.[341,459,462,464,482] The pressure that must develop in the pulmonary artery depends not only on pulmonary arteriolar resistance but also (unlike the systemic circulation) on the pulmonary capillary resistance. Pulmonary function can influence both of these variables. Alveolar hypoxia and acidosis cause reactive pulmonary arterial vasoconstriction, raising pulmonary pressures.[486] This reaction may be particularly important in newborn foals in which vascular resistance is already high.[233] LV function directly influences pulmonary artery pressure because elevation of LA and pulmonary venous pressures places a direct burden on the pulmonary artery and right ventricle.[214] LV failure leads invariably to secondary pulmonary hypertension that can be severe, often with pulmonary pressures exceeding 100 mm Hg. Presumably, other factors such as reactive vasoconstriction (from lung edema) or anatomic changes in the pulmonary vascular tree must develop to sustain such high resistances. In other cases the cause of pulmonary hypertension may not be evident.[487] Accordingly, one must assess elevated pulmonary artery pressures in light of pulmonary wedge (or LV end-diastolic) pressure[272,273] and CO. When pulmonary artery pressure increases, RV and right atrial (RA) pressures must be high to overcome the pressure load. If pulmonary hypertension is chronic, cardiac enlargement, TR, and right-sided heart failure can ensue. The pulmonary occlusion or wedge pressure is an estimate of LV filling pressure and should approximate LV end-diastolic pressure, provided that no obstructions exist in the pulmonary veins or at the mitral valve. The pulmonary artery diastolic pressure also can estimate pulmonary artery wedge pressure provided that the heart rate is normal and pulmonary arterial vasoconstriction (as might occur with hypoxia) is minimal. The pulmonary artery diastolic pressure does not fully equilibrate with the wedge pressure during tachycardia or if pulmonary vasoconstriction and a significant pressure gradient exist between the pulmonary artery diastolic and wedge pressures.[482,485] The wedge pressure is reduced in hypovolemia and is increased during exercise,[482,484] left-sided heart failure,[273,421] severe MR, or after overinfusion of crystalloid or depression of LV function.

TABLE 8-5 Reference Values for Equine Echocardiography

MEASUREMENT	MEAN[*] (cm)	SD[*]	MEAN[†] (cm)	SD[†]
Left ventricle (diastole), right/left	11.90/12.25	0.71/0.72	11.06	1.34
Left ventricle (systole)	7.35	0.72	6.11	0.91
	7.71	0.52	—	—

‡ Left atrial and aortic two-dimensional data from Patteson MW, Gibbs C, Wooton PR et al: Echocardiographic measurement of cardiac dimensions and indices of cardiac function in normal adult thoroughbred horses, Equine Vet J Suppl 19:18–27, 1995.

The RV systolic pressure is lower than that of the left ventricle and usually varies from 40 mm Hg up to 60 mm Hg in standing horses. One often can measure a small gradient (usually 10 to 15 mm Hg) between the ventricular apex and pulmonary artery during systole in normal animals. RV end-diastolic pressure is usually between 10 and 14 mm Hg. The RA and central venous pressures influence RV end-diastolic pressure and preload. Hydrostatic venous blood pressure becomes higher or lower, causing corresponding changes in the RV end-
diastolic pressure if the head of the horse is raised or lowered.[336] As with the left ventricle, depression of 393
contractility reduces the rate of systolic pressure development.[272] Elevated RV systolic pressure is recorded in 394
pulmonary hypertension from any cause, with large VSDs, and with RV outflow obstruction such as that caused

by pulmonic stenosis, tetralogy of Fallot, or large pulmonary valve vegetation.[125] One encounters pathologic elevations in RV diastolic pressure with pericardial disease, pulmonary hypertension, severe right-sided valvular disease, and CHF (Figure 8-24).

Figure 8-24 Recording of intravascular pressure during cardiac catheterization. Right ventricular pressure recordings from a Thoroughbred yearling with atrial fibrillation, pulmonary hypertension, and biventricular congestive heart failure. The pressure waveforms vary because of ventilation and the arrhythmia. Peak pressures exceed 70 mm Hg. In the absence of pulmonic stenosis or a large ventricular septal defect, this indicates pulmonary hypertension. The ventricular end-diastolic pressure also is elevated and is compatible with heart failure.

Mean RA and central venous (vena caval) pressures estimate RV filling pressure and represent a balance between blood volume, venomotor tone, body position, and heart function.[328] Central venous pressure increases significantly in recumbent horses, especially during general anesthesia. Values frequently double from the standing preanesthetic measurement and central venous pressure determinations of 20 to 30 cm of water are common.[466,488] A single measurement of central venous pressure or of the RA pressure profile is of little value. Trends are most important in assessing the volume status and cardiac function of the animal. The x descent of the RA pressure waveform may be replaced by a positive c-v wave in the setting of significant TR; this pressure wave corresponds to a prominent jugular pulsation observed on inspection of the neck.

One can measure CO by thermodilution techniques, arteriovenous oxygen difference, Doppler studies, lithium dilution, or other methods.[*] One most often determines CO while monitoring the effects of fluid and drug therapy on the circulation in critical care situations because CO represents a key variable in oxygen delivery to tissues. Reported values range from 72 to 88 ml/min/kg in standing horses or ponies. One can estimate CO noninvasively using Doppler echocardiographic methods. One can use the mixed venous (pulmonary artery) oxygen content (milliliters of oxygen over deciliters of blood) as an indirect estimate of CO. Mixed venous

samples obtained from pulmonary arterial catheters are superior to venous samples obtained from the jugular or peripheral veins.[384] As CO increases, the tissues extract less oxygen from each aliquot of blood; consequently, the venous oxygen content increases.[235] As CO decreases, tissue extraction of oxygen increases, oxygen content decreases, and the systemic-venous O_2 difference thus widens. One also can use oximetry determinations to detect intracardiac or extracardiac shunting, for example, to identify a left-to-right shunting VSD.

One cannot measure systemic and pulmonary vascular resistances in the intact animal but can calculate these using a variation of Poiseuille's law. The general formula for calculation of resistance is as follows:

$$\text{Vascular resistance} = \frac{\text{Mean arterial pressure} - \text{Mean atrial pressure}}{\text{Cardiac output}}$$

where one measures CO in liters per minute by thermodilution. The pressures used are mean aortic pressure and mean RA pressure for the systemic vascular resistance and mean pulmonary arterial pressure and mean pulmonary wedge pressure for the pulmonary vascular resistance. One may add correction values to convert resistance to centimeter-gram-second units.[490] Because mean arterial pressure is similar between horses of different size, calculated vascular resistance is normally higher in smaller horses and ponies. Mechanisms that increase systemic vascular resistance include sympathetic activation, activation of the renin-angiotensin system, and the release of other vasoactive hormones into the blood, including arginine vasopressin (antidiuretic hormone) and epinephrine.[70] The pulmonary vascular resistance is tied to pulmonary vascular anatomy, age, total lung capillary resistance, LA pressure, and degree of pulmonary vascular constriction. The latter is controlled by the tension of alveolar oxygen and local mediators including nitric oxide and endothelin.

8.4.6 LABORATORY STUDIES

Cardiovascular disorders may develop as a result of systemic or metabolic diseases such as electrolyte disturbances or septicemia. Conversely, circulatory failure or cardiovascular infections may alter routine laboratory tests. Prerenal azotemia and hyponatremia, for example, may be detectable in the horse with CHF, 394
especially after diuretic therapy. Myocardial enzymes or proteins such as troponin may be released in the 395
circulation from primary or secondary cardiac muscle injury, as might occur with hypotension and ischemia.

Box 8-4 gives an overview of the laboratory studies useful in assessing and managing cardiovascular diseases. A routine complete blood count and fibrinogen, biochemical profile, and urinalysis are indicated in horses with arrhythmias or heart failure or with clinical evidence of endocarditis, pericarditis, vasculitis, or pleural effusion. Additional studies including blood cultures, blood gas tensions, other electrolytes (e.g., magnesium), oxygen saturation, cytologic examination and culture of pericardial effusates, serum troponin I concentrations, and myocardial isoenzymes of creatine kinase or lactate dehydrogenase are indicated in selected cases. Monitoring of serum or plasma drug concentrations, especially quinidine and digoxin, are appropriate when using these drugs to treat patients with heart disease. Application of these studies is discussed under specific diseases.

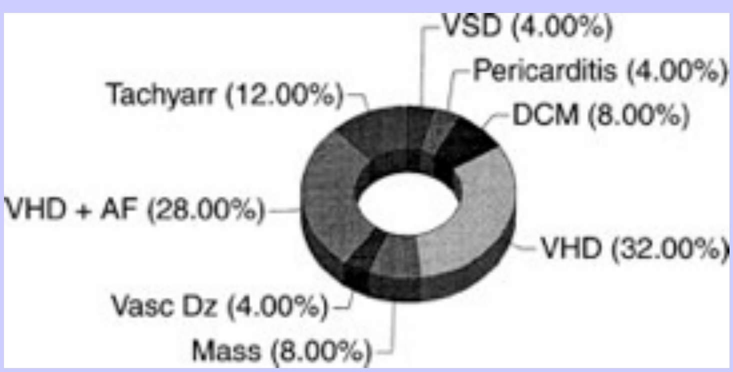
8.5 Congestive Heart Failure

8.5.1 CAUSES

Heart failure is a clinical syndrome characterized by limited CO, increased neurohormonal activity, renal sodium retention, edema in tissues, and transudation of fluid into serous body cavities. The neurohormonal and renal abnormalities that characterize heart failure have not been studied extensively in horses but are probably similar to those reported in other species.[98] Probably the most characteristic clinical feature of heart failure, short of exercise intolerance, is the increase in venous pressures identified by physical examination or by cardiac catheterization. One recognizes the typical horse with cardiac failure when heart failure progresses to the overtly congested phase, with fluid accumulation.

Most cardiac lesions in horses are not severe enough to lead to CHF, and this syndrome is not common in equine practice. Nevertheless, CHF does develop in foals and mature horses as a result of diverse disorders, including congenital malformation, severe degenerative valvular disease, valvulitis, bacterial endocarditis, dilated cardiomyopathy, myocarditis, myocardial necrosis, pericardial disease, vascular rupture, pulmonary hypertension, artery obstruction, or persistent tachyarrhythmia.[104,491,492] The most common cause of CHF in horses is valvular heart disease, which often is complicated by atrial fibrillation (Figure 8-25). In addition to structural lesions of the heart and blood vessels, primary electric disturbances, particularly sustained atrioventricular dissociation caused by junctional or ventricular tachycardia, can reduce myocardial function, decrease CO, and lead to CHF.[493] This is especially likely when the heart rate exceeds 100 beats/min for many days. Resolution of CHF in such cases may be possible if antiarrhythmic therapy is successful.

Figure 8-25 Graph demonstrating the overall causes of congestive heart failure in 25 horses at a referral teaching hospital as a percentage of the total number of cases of equine congestive heart failure. *Tachyarr,* Tachyarrhythmia; *VSD,* ventricular septal defect; *DCM,* dilated cardiomyopathy; *VHD,* valvular heart disease; *Mass,* mass lesion; *Vasc Dz,* vascular disease; *VHD + AF,* valvular heart disease and atrial fibrillation. (Data from Ohio State University Veterinary Hospital.)



8.5.2 CLINICAL RECOGNITION

CHF may develop suddenly or gradually. Peracute heart failure can occur following rupture of mitral valve chordae tendineae or consequent to acute bacterial endocarditis of a cardiac valve. Heart failure may progress rapidly in a foal with a large VSD as the pulmonary vascular resistance falls in the weeks following birth. Chronic valvular regurgitation may, after many years, lead to CHF, although only a small number of horses with degenerative valvular disease develop CHF. Some lesions, which might otherwise be well tolerated, can cause heart failure if demands for CO increase. Examples of such demands include strenuous work, severe anemia, or persistent fever. Pregnancy is another example: the volume expansion and increased demands for CO in the latter stages of gestation may precipitate CHF in a mare with previously compensated heart disease. Development of atrial fibrillation in a horse with underlying structural disease, such as dilated cardiomyopathy or MR, can precipitate CHF. Such cases are distinguished from the more typical case of atrial fibrillation by the presence of persistent, resting tachycardia and identification by echocardiography of structural lesions and cardiomegaly.

The clinical features of CHF are easily recognizable,[350] and determination of the underlying cause of heart disease is not difficult if one combines careful auscultation with available diagnostic methods, particularly 395
echocardiography and ultrasound examination of body cavities.[*] Presenting clinical signs can vary but may 396
include exercise intolerance, poor recovery after exercise, weight loss, coughing, tachypnea, ventral edema, and even colic-like signs.

The clinical signs of right-sided CHF include resting tachycardia and prominent S_3 along with generalized ventral, preputial, pectoral, and limb edema. Isolated limb edema, which is so common in hospitalized horses, is not a sign of CHF. Nor should ventral edema, in the absence of generalized venous distention, suggest a diagnosis of CHF. This finding should prompt consideration of other disorders including vasculitis. Scrutiny of the jugular and other superficial veins generally makes the recognition of right-sided CHF straightforward, because affected horses demonstrate elevated venous pressure and pathologic jugular pulses and filling. The most common causes of isolated right-sided CHF are tricuspid or pulmonic valve lesions as with valvular endocarditis, diffuse pulmonary vascular disease, and pericardial disease. In most cases a prominent murmur of TR is evident over the right thorax. When pulmonary hypertension underlies right-sided heart failure, the tricuspid murmur may be especially loud and the pulmonic component of S_2 tympanic. Because right-sided heart failure often develops consequent to pulmonary hypertension caused by left-sided heart failure, left-sided murmurs are common. Another common association of right-sided CHF is persistent cardiac arrhythmia, such as atrial fibrillation, superimposed on structural heart disease of any form. One must distinguish cranial mediastinal lymphosarcoma and cranial thoracic masses from RV failure.[508] Examination with two-dimensional echocardiography and thoracic ultrasonography facilitates diagnosis.

Recognizing isolated left-sided heart failure, which causes pulmonary venous congestion and pulmonary edema, can be more difficult. In these cases, heart sounds and murmurs may be difficult to evaluate because of loud airway sounds or crackles. If a cardiac murmur is present but missed, one may entertain an erroneous diagnosis of pneumonia. Again, resting tachycardia and loud S_3 are typical in these cases, and echocardiographic examination of the horse is useful. Typical findings in left-sided CHF are dilation and rounding of the left atrium and ventricle and often dilation of the pulmonary artery caused by pulmonary hypertension. Careful examination may demonstrate anatomic lesions of the aortic root, ventricular septum, left heart valves, or chordae tendineae. Fulminant left-sided CHF can lead to coughing and expectoration of edema—a grave sign in most horses.

Biventricular heart failure most commonly occurs when severe left-sided heart disease results in chronic CHF. The clinical signs of advanced biventricular heart failure include resting tachycardia (usually >60 beats/min), loud ventricular filling sound, subcutaneous edema, tachypnea (from pulmonary edema or pleural effusion), varying amounts of ascites and pleural effusion, a small pericardial effusion, jugular distention, and abnormal jugular pulsations. In most cases a systolic murmur of TR and often murmurs typical of mitral or aortic valvular regurgitation or a VSD are present. Chronic biventricular CHF frequently is characterized by lethargy and also by loss of body condition.

One must understand that *chronic* left-sided CHF in the horse is likely to cause interstitial lung edema and pulmonary hypertension. The magnitude of pulmonary hypertension is often impressive, with systolic pulmonary artery pressures exceeding 80 mm Hg in many cases. The mechanisms by which the lung accommodates such severe and chronic elevations in pulmonary venous pressures without development of alveolar edema are only speculative to date, but pulmonary vascular resistance likely increases out of proportion to the increase in wedge pressure (as occurs in some human patients with chronic left-sided heart failure). This accommodation might be related to anatomic or remodeling changes in pulmonary veins or arteries induced by chronic elevation of LA pressure. Thus the clinician should anticipate signs of right-sided CHF even when the primary lesion can be identified on the left side of the heart. This finding can be attributed to RV dilation and TR, which are caused by increased pulmonary vascular resistance. Furthermore, generalized fluid retention is a characteristic of chronic CHF, and some of this retained fluid undoubtedly pools in systemic venous beds and third spaces.

Clinical findings of severe pulmonary hypertension caused by left-sided CHF include a loud, tympanic, pulmonary component of S_2 (heard cranioventral to the aortic valve area), a systolic murmur and jugular pulse of tricuspid insufficiency, and dilation of the pulmonary artery, which can be identified by two-dimensional echocardiography. Further scrutiny allows one to identify LA dilation and a lesion of the left heart valves, aorta, or left ventricle. Investigation of the exact cause of CHF involves integration of physical examination findings with routine diagnostic studies such as electrocardiography and echocardiography. Thoracic radiographs may be helpful and can demonstrate increased pulmonary vascularity, pulmonary infiltration near the hilus, pleural effusion, and rounding or enlargement of the cardiac silhouette. Echocardiography is essential to identify structural lesions, quantify cardiomegaly, and measure systolic ventricular function. Doppler echocardiography can document abnormal flow patterns and predict pulmonary artery pressures (using the Bernoulli relationship), provided that one can record the velocity of any TR or pulmonary insufficiency jets faithfully. The ECG is required to evaluate cardiac arrhythmias.

8.5.3 THERAPY

Therapy for CHF is realistic for potentially reversible disorders such as pericarditis or sustained ventricular tachyarrhythmia. Therapy also may be feasible for valuable breeding stallions and mares, mares that develop CHF during gestation, or horses and ponies kept as pets.[136,350,509] Before therapy can commence, one needs an accurate diagnosis. For example, pericardiocentesis (not cardiac drugs) would be appropriate initial management of cardiac tamponade; thereafter, one could consider surgical drainage of the effusion (using drainage tubes) or a pericardiectomy.[83,84,91,510,511] Antibiotics would be essential for treating bacterial endocarditis or infective pericarditis. Sustained junctional and ventricular tachyarrhythmias may lead to low CO and a potentially reversible dilated cardiomyopathy. Antiarrhythmic therapy with quinidine, magnesium sulfate solution,

lidocaine, propafenone, or procainamide may be effective for treating some of these arrhythmias, and with resumption of normal rhythm, CHF may be reversed.

Furosemide,[257,499,512,513] digoxin,[*] and vasodilators or angiotensin-converting enzyme (ACE) inhibitors[145,156] are the mainstays for short- and long-term management of CHF (Table 8-6). One must titrate the diuretic dosage to mobilize edema and prevent its recurrence and improve respiratory effort when pulmonary edema is evident, and one should control the dosage to prevent prerenal azotemia or electrolyte disturbances. One eventually may discontinue diuretic therapy in some horses. Depending on urgency and ability to monitor ECG rhythm, one can administer digoxin initially as a loading dose or by using an intravenous or oral maintenance regimen. The reported elimination half-life of digoxin has not been consistent (7.2 to 28 hours) and probably relates to the clinical state of the animals studied. As expected, oral doses of digoxin are higher because of lower bioavailability (20%).[263] Long-term digoxin therapy involves once or twice daily oral administration, usually mixed with molasses and some grain. One should monitor chronic digitalization by measuring serum digoxin concentration and evaluating a blood sample (drawn between 8 and 12 hours after the previous dose). Therapeutic values for the trough plasma level generally are considered to be between 1 and 2 ng/ml. Periodic cardiac examinations, measurements of serum biochemistries (creatinine, electrolytes), and recordings of ECG rhythm strips are warranted during any long-term course of therapy.

Published experience using vasodilators and ACE inhibitors in horses is limited. One might consider hydralazine therapy[236] in the initial management of severe MR caused by ruptured chordae tendineae or endocarditis, because systemic arterial dilation can reduce the mitral regurgitant fraction greatly. ACE inhibitors have been prescribed for treatment or prevention of CHF in horses with apparent clinical success. Clinical improvement has occurred in many horses with enalapril[516] administered at 0.5 mg/kg orally twice daily and is affordable for clients with the generic formulation. Although the cost may be prohibitive, ramipril also has been tolerated in some cases.[517]

For horses with cardiomyopathy or valvular disease or in pregnant mares with CHF, the development of atrial fibrillation may precipitate CHF. Furosemide and digoxin can control CHF effectively in many of these animals. The use of ACE inhibitors is contraindicated in pregnant mares, but one can use hydralazine without any demonstrable ill effects on the fetus. Quinidine generally is contraindicated in such cases, although horses sometimes may convert after the resolution of CHF by medical therapy. One may achieve reasonable long-term control of CHF, thus permitting a comfortable existence for the horse and, in the case of breeding animals, continued reproductive service.

Prognosis in CHF always is guarded when irreversible structural heart disease is the cause of failure; thus the long-term outcome for life is poor. Of course, the horse with CHF requires rest to reduce demands on the heart and should never be worked or ridden because of the risk of pulmonary artery rupture or syncope. Valuable horses may be used for breeding; however, pregnant mares are likely to be difficult to control in the later stages of gestation, probably related to the volume expansion that accompanies the later stages of pregnancy.

8.6 Congenital Heart Disease

The prevalence of congenital heart disease in the overall equine population is unknown. In one survey of causes for neonatal death or euthanasia in 608 cases, the prevalence of congenital heart disease was 3.5%.[150] Congenital heart disease often is considered when a foal, weanling, or immature horse is identified with a prominent cardiac murmur, cyanosis, or signs of CHF.[316] A variety of cardiac malformations have been identified.[*] Theoretically, a

great number of cardiac malformations could occur, including anomalies of venous drainage, atrial situs or septation, atrioventricular connection, atrial or ventricular development (including formation of the two 397
atrioventricular valves), ventricular outflow tracts, semilunar valves, and great vessels.[547,548] Furthermore, 399
abnormal segmental connections might occur leading to discordance in the path of systemic or pulmonary venous return relative to the pulmonary artery or aorta. These abnormalities include transposition of the great vessels and double-outlet ventricle, in which both great vessels exit the right or LV cavity. However, practically speaking, the most common cardiac malformations in horses involve shunting of blood at the atrial or ventricular regions.

TABLE 8-6 Drug Therapy of Heart Disease

DRUG	FORMULATION	DOSAGE FORMS	INDICATIONS	USUAL DOSE
Digoxin	Lanoxin	Lanoxin 0.25 mg/ml, 2-ml vials; Lanoxin tablets 0.5 mg	CHF,* atrial tachyarrhythmias, control of rapid ventricular response in atrial fibrillation/flutter	IV maintenance dose for treatment of CHF: 0.22 mg/100 kg body mass, q12h
				Oral maintenance dose for chronic therapy of CHF or for control of ventricular rate response in atrial fibrillation: 1.1–1.75 mg/100 kg body mass, q12h
				IV maintenance dose for control of ventricular rate response in atrial fibrillation (neither CHF nor renal failure is present): 0.22–0.375 mg/100 kg body mass, q12h
				IV loading dose: 0.44–0.75 mg/100 kg body mass, q12h for two doses (not commonly used)
Procainamide	USP	100 or 500 mg/ml for injection; 500-mg capsules	Ventricular arrhythmias, atrial arrythmias	25–35 mg/kg q8h per os
	Pronestyl			1 mg/kg/min IV to a maximum of 20 mg/kg
Lidocaine	Xylocaine without epinephrine	2% solution, 20 mg/ml concentration	Ventricular tachycardia	0.5–1.5 mg/kg slowly IV; can repeat in 15 minutes
				Constant IV infusion of 25–50 g/kg/min
